

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

INDEX TO VOLUME CIX.

THE Index of the Boston Medical and Surgical Journal is arranged by authors and by subjects. Articles relating to the circulatory, respiratory, or nervous system, are to be found under those heads respectively. This method of indexing is that followed by the Editors of the *Index Medicus*, and is believed to be the most satisfactory plan which can be adopted. F. H. B.

- Abbot, S. L.** Rheumatism in the horse; treatment by salicylate of soda, 209.
- Abbott, S. W.** Recent progress in public hygiene and State medicine, 442.
- Abortion.** Two cases of abortion, Stedman, G., 50, 60.
- Abscess.** Chronic abscess of the mammary gland, Crandall, C. R., 224; a case of cold abscess, Newton, R. C., 246; remarks on chronic abscess of the pelvis, Byford, W. H., 323.
- Adams Nervine Asylum,** 258.
- Adulterated Drugs.** The prosecution of manufacturers of adulterated drugs, 573.
- Adulteration.** Report upon the adulteration of food and drugs,avenport, B. F., 536.
- Alaska** from a medical point of view, 448.
- Alcoholism.** A neglected field of medical supervision, Shute, C. B., 485, 509.
- Alexander.** Prolonged suspension of vitality due to atropia injected hypodermically, 141.
- Alopecia Prematura,** 334.
- Althaus, J.** The risks of massage, 279.
- Ambulance Service,** 307.
- Amory, E.** Letter from St. Petersburg, 596.
- Anemia.** Iron and arsenic in anemia and chlorosis, Willcocks, 261.
- Anatomy.** The Parkman professorship of anatomy in the Harvard Medical School, 91; the use of fusible metal in making injections for corrosion anatomical preparations, Mixter, J. S., 156; recent progress in anatomy, Dwight, T., 225; clinical lecture on failure of sexual development, Thomas, T. C., 318.
- Anthony, W. E.** Management of the third stage of labor, 299.
- Anus Medicus,** 614.
- Anus.** Iodoform in fissure of the anus, Becker, A. R., 354.
- Apartment Houses.** Dangers to the public health from the erection of high apartment houses, Vanderpoel, 570.
- Apoplexy of the cerebellum,** Hurd, E. P., 195.
- Archambault.** Treatment of whooping-cough, 239.
- Army and Navy.** Surgical appliances for disabled soldiers and sailors, Crane, C. H., 236; annual report of the surgeon-general United States army, 1883, 546.
- Ascites.** Obscure case of ascites and anasarca, Minot, F., 154.
- Asphyxia,** hot bath in, 330.
- Atkinson (Baltimore).** Multiple cachectic ulcerations, 252.
- Atropia.** Prolonged suspension of vitality due to atropia injected hypodermically, Alexander, 141.
- Bacillus.** A contribution to the study of the tubercle-bacillus, Ernst, H. C., 100, 121.
- Baltimore.** Letter from Baltimore, 19.
- Bancroft, C. P.** Large vesical calculus in an insane patient; removal through vagina; death on sixth day; autopsy, 603.
- Banks, Charles E., P. A. Surgeon, M. H. S.** The appropriation to prevent the spread of epidemic disease, 621.
- Bartholow, R.** Enteric paraplegia, 562.
- Batchelder, D. H.** Death from carbolic acid, 261.
- Bate, S.** Culture and nature, 463.
- Bathing.** Sea bathing, 70.
- Becker, A. R.** Iodoform in fissure of the anus, 354.
- Bibliography.** Aitken, W., A Complete Hand-Book of Treatment, arranged as an Alphabetical Index of Diseases to Facilitate Reference, and containing nearly One Thousand Formulae, 399; Allen's Human Anatomy, 16; Arkansas, First Annual Report of the State Board of Health, 204; Army, The Medical and Surgical History of the War of the Rebellion, Part III., Vol. II., Surgical History, 87; Beard, G. M., and Rockwell, A. D., A Practical Treatise on the Medical and Surgical Uses of Electricity, 425; Bervet, F., Du Diagnostic de l'Ectopie Rénale, 375; Boston Board of Health, Annual Report, 1882-1883; Boston City Hospital, Nineteenth Annual Report, 161; Boston Lunatic Asylum, Forty-fourth Annual Report, 18; Bourneville, L'Année Médicale, 125; Bourneville, Recherches Cliniques et Thérapeutiques sur l'Epilepsie, l'Hystérie, et l'Idiotie, 514; Buckingham, T. R., Insanity considered in its Medico-Legal Relations, 692; Bull, O. B., Chromatoptometrisk Tabel, Chromatoptometrical Table, 159; Carpenter, W. B., The Microscope and its Revelations, 231; Colorado State Medical Society, Transactions, 1883, 473; Corning, J. L., Brain-Rest, 158; Cowell, G., Lectures on Cataract: Its Causes, Varieties, and Treatment, 159; Curtis, E., Manual of General Medicinal Technology, including Prescription Writing, 692; Dunglison, R. J., The Practitioner's Ready-Reference Book, 38; Dunglison, R. J., A New School Physiology, 255; Edees, R. T., Therapeutic Hand-Book of the United States Pharmacopoeia, 38; Erb, W., Hand-Book of Electro-Therapeutics, 425; Ear, Diagrams for Recording Diseases of the Ear, 447; Fritch, H., The Diseases of Women, 447; Galton, F., Inquiries into Human Faculty and its Development, 520; Ganges, S., On the Treatment of Wounds and Fractures, 611; Gibbs, H., Practical Histology and Pathology, 592; Gilliam, D. T., The Essentials of Pathology, 425; Gray, H., Anatomy, Descriptive and Surgical, 305; Hamilton, A. McL., Types of Insanity, 612; Hamilton, D. J., On the Pathology of Bronchitis, Catarrhal Pneumonia, Tubercle and Allied Lesions of the Human Lung, 323; Hammond, W. A., A Treatise on Insanity in its Medical Relations, 157; Hewitt, G., The Pathology, Diagnosis, and Treatment of the Diseases of Women, 591; Holmes, O. W., Medical Essays, 1842-1882, 153; Hopkins, W. B., The Roller Bandage, 350; Horwitz, O., A Compend of Surgery for Students and Physicians, 350; Hudson, W. H., Sea-Sickness: Its Cause, Nature, and Prevention without Medicine or Change in Diet, 613; Hun, H., A Guide to American Medical Students in Europe, 544; Kennedy, W. S., Oliver Wendell Holmes, Poet, Littérateur, Scientist, 159; Kitchen, J. W. M., Student's Manual of Diseases of the Nose and Throat, 592; Klein, E., Elements of Histology, 613; Leache, S., Die Anämie, 620; Massachusetts State Board of Health, Lunacy, and Charity, Report and Papers, 1883, 497; Massachusetts Registration Report for the year 1882, 493; Mitchell, C. P., The Treatment of Wounds, as based on evolutionary laws, 562; Nettleship, E., Student's Guide to Diseases of the Eye, 16; New Hampshire Medical Society, Ninety-third Annual Session, 473; New Hampshire, First Annual Report of the State Board of Health, 204; New York, Second Annual Report of the State Board of Health, 204; Ontario, State Charities Aid Association, No. 32, 543; Oppert, F., Hospitals, Infirmeries, and Dispensaries, 543; Pennsylvania, Transactions of the Medical Society of the State of, XV., 350; Philadelphia Medical Times, 332; Parrish, J., Alcoholic Intoxication from a Medical Stand-Point, 159; Pitcher, L. S., The Treatment of Wounds, 613; Pitzer, G. C., Electricity in Medicine and Surgery, 136; Pomeroy, O. D., The Diagnosis and Treatment of Diseases of the Ear, 620; Post, E., Vanderpoel, Pitcher, Hun, Wey, Agnew, etc., An Ethical Symposium, 692; Potter, S. O. L., Quia Compend of Viscera, 350; Ross, J., A Treatise on the Diseases of the Nervous System, 613; Sattler, E. E., A History of Tuberculosis from the Time of Syllius to the Present Day, 447; Spitzka, Insanity: Its Classification, Diagnosis, and Treatment, 543; Stearns, H. G., Insanity: Its Causes and Prevention, 153; Surgeon-General's Office, U. S. A., Index Catalogue, No. IV., 352; Taylor, A. S., The Principles and Practice of Medical Jurisprudence, 64; Thompson, W. G., Training-Schools for Nurses, with Notes on Twenty-Two Schools, 399; Welch, F. H., Enteric Fever: Its Prevalence and Modifications: Aetiology: Pathology and Treatment, 612; West, S., How to Examine the Chest, 613; Wood, H. C., A Treatise on Therapeutics, 279; Ziegler, E., A Text-Book of General Pathological Anatomy and Pathogenesis, 473.
- Bigelow, H. J.** Presentation of a bust of Professor Bigelow, 404.
- Billings, F. S.** Hemaphrodismus spurius maculinus bovis, 86.
- Biography.** Arnold, G. J., 503; Blumenthal, C. S., 330; Crane, C. H., 384, 626; Depaul, 523; Dwight, T., 91; Ellis, C., 598; Fitts, S. E., 430; Fleming, J. A., 396, 353; Harvey, W., 475; Jackimovics, 232; Joyce, R. D., 479; Lente, F. D., 457; Lord, F. D., 599; Mead, E., 139; Mead, M. E., 508; Murray, R., 527; Oliphant, R. W., 408; Pacini, F., 162; Sims, J. M., 496, 501; Smith, N., 804; Trask, J. D., 259; Wright, C., 259.
- Blackwood, W. R. D.** An interesting case of femoral hernia in an aged patient; strangulation; operation, with cure, 344.
- Blodgett, A. N.** Specimen of ovaries and uterus amputated at the cervix, 83; the third tonsil and diphtheria, 255.
- Boardman, W. E.** Pseudo-membranous enteritis, 374, 516; a case of malignant disease of the uterus, 458, 494.
- Bolles, W. P.** Report on materia medica and pharmacy, 195.
- Boston Dispensary,** 331.
- Botetz, C.** Tumors in the temporal region, 93.
- Bowditch, H. I.** Treatment of double pneumonia by inhalation of oxygen, 156; medical tramps, 585; arrested phthisis, 569.
- Bradford, E. H.** Cases in the service of Dr. Fifield, 59; the effect of recumbency on the length of the spine, 245; severe cases of club-foot, 273; report on progress in surgery of deformities and diseases of joints, 344; calculus from a child ten years old, 567.
- Brannan, J. W.** Peptonized milk as a curative agent in acute dyspepsia, 54.
- Breast.** Carcinoma (scirrhus) of the breast, Girvin, R. M., 35; chronic abscess of the mammary gland, Crandall, C. R., 224; recurrent scirrhus of the male breast, De Schweinitz, G. E., 471; sarcoma of the breast, De Schweinitz, G. E., 573.
- Bright's Disease.** Professor Semmola on the pathogeny of Bright's disease, 113; urinary casts outside of Bright's disease, 130.
- British Army in the Egyptian expedition;** medical department, 65; the British army hospital services inquiry committee, 89.
- Brown, F. H.** Plain words about the Medical Register for New England, 549.
- Brown-Sequard.** Cataleptic state of the muscles, 358.
- Bruce.** Cerebral tumor mistaken for hysteria, 209.
- Bruen, E. T.** Case of sarcoma occupying the anterior mediastinum, 542.
- Buck, W. E.** Note on disinfectants, 523.
- Bull.** Surgery of the lungs, 355.
- Burn.** Plastic operation for burn, Porter, C. B., 35.
- Burrell, H. L., and Watson, F. S.** Contraction of the knee-joint treated by splints, 202.
- Bush, J. F.** Case of nasal diphtheria, 61.
- Byford, W. H.** Remarks on chronic abscess of the pelvis, 323.
- Cabot, A. T.** A contribution to the treatment of empyema, 145, 153; recent progress in surgery, 605.
- Calculus.** A case of renal calculus, oxalate of lime, Musser, J. H., 86; the rapid evacuation of stone from the bladder after crushing, Otis, F.

- N., 467; calculus from a child ten years old, Bradford, E. H., 567; large vesical calculus in an insane patient, Bancroft, C. P., 603.
- Campbell, H. F.** Menstruation after extirpation of the ovaries, 820.
- Cancer.** Case of "cancer-drawing," Dixon, R. B., 70; carcinoma (scirrhus) of the breast, Girvin, R. M., 55; carcinoma (scirrhus) of the rectum, Musser, J. H., 35; sarcoma of the bladder, Musser, J. H., 86; operative treatment of cancer of the tongue, 120.
- Captain.** Prehistoric trephining, 524.
- Carbolic Acid.** Death from carbolic acid, Batchelder, D. H., 251.
- Carr, G. W.** Surgical cases in Rhode Island Hospital, 183.
- Casts.** Urinary casts outside of Bright's disease, 190.
- Caswell, E. T.** Surgical cases in Rhode Island Hospital, 183; fibroma of the vagina, 151.
- Catarrh.** The treatment and curability of chronic uterine catarrh, Mundé, P., 238.
- Cerebellum.** Apoplexy of the cerebellum, Hurd, E. P., 195; tumor of cerebellum, Seymour, W. W., 200.
- Cervix.** Clinical report on cases of lacerated cervix, Warren, J. W., 197, 223.
- Chambord.** The mistaken diagnosis in the case of the Comte de Chambord, Vulplan, 451.
- Chancreous Virus,** attenuation of, 381.
- Channing, W.** Report on recent progress in the construction of insane hospitals and management of the insane, 452.
- Charcot.** On some local nervous manifestations, 212.
- Chemistry.** Recent progress in medical chemistry, Hills, W. B., 130; on certain unrecognized forms of lead-poisoning, and on the possibility of mistaking bismuth for lead in urine analysis, Putnam, J. J., 815; notes of progress in physiological chemistry, Warren, J. W., 418.
- Chicago.** Medical expert testimony in the Chicago lard investigation, 68.
- Children.** Some observations on the salivary digestion of starch by infants, Keating, J. M., 31; a case of laudanum-poisoning in an infant one day old, Stedman, G., 50; a note on the feces of starch-fed infants, Randolph, N. A., 52; recent progress in diseases of children, Rotch, T. M., 79, 108; infantile urethral stricture, Whitney, J. O., 295; couvreuse, or mechanical nurse, 357; abdominal tumors in children, Whittier, E. N., 505.
- Chloroform** in labor, Woolen, G. V., 328.
- Chlorosis.** Iron and arsenic in anemia and chlorosis, Willcocks, 261.
- Cholera.** Epidemic cholera, 137; cholera germ, 474.
- Church, M. D.** A case of suppurative hepatitis due to a pin in the vermiform appendix, 269; notes of a peculiar case in which the autopsy showed congenital absence of the left kidney, 538.
- Circulatory System.** Extreme mitral stenosis, death resulting in a few months from sequential lesions without general dropsy, Eskridge, 18; theories regarding the mechanism of the inorganic cardiac murmurs, Garland, G. M., 25, 34; the diagnosis of the so-called "functional murmurs," Shattuck, F. C., 28, 34; a new interpretation of Flint's mitral direct or presystolic murmur without mitral lesions, Keyt, A. T., 30; kidneys and heart from a case of chronic Bright's disease, Musser, J. H., 62; aortic valvular disease due to the combined action of strain and rheumatism, Musser, J. H., 63; clinical lecture on organic disease of the heart, Flint, A., 139; a case of thrombosis of the straight cerebral sinus, Rotch, T. M., 174; presystolic murmurs, organic and inorganic, Sanson, A. E., 190; apoplexy of the cerebellum, Hurd, E. P., 195; hemorrhage following tonsillectomy, Otis, W. J., 227; division of the internal jugular vein, Ingalls, W., 230; tricuspid regurgitation, Lynch, J. S., 237; controlling hemorrhage in amputation at the hip-joint, Lloyd, J., 262; the negative arterial pulse, Keyt, A. T., 340; heart complication in acute articular rheumatism, Flint, A., 409; phthisis with absence of pericardium and malposition of uterus, Hughes, W. E., 472; case of death from heart clot following etherization, Minot, F., 560, 568; a case of sudden death due to hemorrhage from the hepatic vein, Hoyt, A. F., 584, 587; probable progressive hemorrhage into the bowel depending on general disorganization of the blood, Hodges, R. M., 608.
- Cirrhosis.** Shrinkage in cirrhosis of the liver, Seymour, W. W., 259.
- Clark, F. C.** Education in the medical profession, 260.
- Clarke, A. P.** Cerebral erysipelas, 128.
- Clarke, H. B.** "A case of delayed putrefaction," 598.
- Claxton.** Case of cancer of the liver, 424.
- Cleanliness** in surgical operations, Sutton, R. S., 302.
- Climate** of Santa Barbara and the Northern Pacific Coast, 354.
- Clonus.** Ankle clonus in relation to the height of the individual, James, A., 94.
- Club-foot.** Severe cases of club-foot, Bradford, E. H., 278; club-foot apparatus in cases of contracture, Seyre, L. A., 384.
- Code of Ethics.** New York, 348.
- Colorado climate** for consumptives, 622.
- Color-Blindness.** The quickest, surest, and most practical method of ascertaining defects in the chromatic sense, Jeffries, B. J., 38.
- Concussion** of the spine, Putnam, J. J., 217.
- Connecticut.** Sanitary report of the Connecticut State Board of Health, 71; typhoid fever in Connecticut, 452.
- Consumption** in New England, Hurd, E. P., 265.
- Consumptives,** Colorado climate for, 622.
- Copper** as a prophylactic against cholera, typhoid fever, etc., 330.
- Corning, J. L.** Cerebral exhaustion, 570.
- Coroners.** The coroners must go, 280; medical examiners, 300; medical examiners in Rhode Island, 311.
- Couvreuse,** or mechanical nurse, 357.
- Crandall, C. R.** Chronic abscess of the mammary gland, 224.
- Craue, C. H.** Surgical appliances for disabled soldiers and sailors, 236.
- Cremation societies** for the propagation of cremation, and their hobby, 306.
- Cutaneous System.** Case of pemphigus pruriginosus, Garland, G. M., 131; treatment of acne, Piffard, 251; general exfoliative dermatitis, Graham, 252; impetigo contagiosa, Stetwagon, 252; multiple caecotic ulcerations, Atkinson, 253; experiments in the use of naphtol, Van Harlingen, 252; leprosy, Fox, 253; Paget's disease or malignant papillary dermatitis, Sherwell, 253; pathogenesis of drug eruptions, Morrow, 253; changes observed in the non-ulcerating tubercular syphilide, Taylor, R. W., 253; pseudo-porriasis and porriasis of the palm, Sherwell, 254; a study of the coincidence of syphilitic and non-syphilitic affections of the skin, Hyde, 254; peculiar appearance of the initial lesion of syphilis at the beginning, Taylor, R. W., 254; the value of a lotion of sulphide of zinc in the treatment of lupus erythematosus, Duhning, L. A., 254; a case of alnum, Duhning, L. A., 254; a peculiar papillary disease of the skin, Hardaway, 254; lymphangioma cutis, Graham, 254; hyperidrosis manuum, Smith, H. A., 262; probable epithelioma cured by astringent washes, Francis, S. W., 300; exfoliative dermatitis, Perry, T. W., 300; pulmonary complications of erythema nodosum, Fée, G., 311; was it a coincidence? (contagion of eczema), 332; alopecia prematura, 334; progress in dermatology, Tilden, G. H., 333; the treatment of psoriasis, Van Harlingen, A., 438; purpura from quinine, Wigglesworth, E., 587.
- Cutler, E. G.** A case of croupous pneumonia, occurring in a child with serious mitral disease; recovery, 78, 84.
- Davenport, B. F.** Report upon the adulteration of food and drugs, 586.
- Davenport, F. H.** Recent progress in gynecology, 55.
- Deaf-Mutes.** The sense of dizziness in deaf-mutes, James, 356.
- Death** from the entrance of air into the uterine veins, Draper, F. W., 516; death from heart-clot following etherization, Minot, F., 560.
- Deaths,** registration of. Turner, H. E., 301.
- De Blois, T. A.** Insufflators, 13.
- Decapitating Instrument,** new, Dixon, R. B., 239.
- Delanfield, F.** Typhoid fever in New York, 517.
- Derby, H.** Results of the examination of the refraction of four consecutive classes at Amherst College, 110.
- Dermatitis.** Exfoliative dermatitis, Perry, T. W., 300.
- De Schweinitz (Philadelphia).** Recurrent scirrhus of the male breast, 471.
- Diabetes.** Bromide of arsenic in diabetes mellitus, 284; on the treatment of diabetes, Dujardin-Beaumont, 457, 481; diet in diabetes, 522.
- Dietetics** for the sick, Seltzer, C. W., 317.
- Digestive System.** Some observations on the salivary digestion of starch by infants, Keating, J. M., 31; carcinoma (scirrhus) of the rectum, Musser, J. H., 35; eserin in diarrhoea, Eechle, 41; a note on the feces of starch-fed infants, Randolph, N. A., 52; peptonized milk as a curative agent in acute dyspepsia, Brannan, J. W., 54; the diagnosis of teniae intestinales, 119; operative treatment of cancer of the tongue, 120; obscure case of ascites and anasarca, Minot, F., 154; iodoforn for fissure of the anus, Hay, T., 211; shrinkage in cirrhosis of the liver, Seymour, W. W., 259; a case of suppurative hepatitis due to a pin in the vermiform appendix, Church, M. D., 269; the treatment of atonic dyspepsia, Fothergill, J. M., 236; an interesting case of femoral hernia in an aged patient, Blackwood, W. R. D., 344; iodoforn in fissure of the anus, Becker, A. K., 354; the significance of appearances of the tongue, Hutchinson, J., 357; pseudo-membranous enteritis, Boardman, W. E., 374, 516; a case of fatty liver in connection with ascites from hepatic cirrhosis, Flint, A., 410; specimen of very large ulcer of the stomach with unusual features, Dulles, C. W., 423; a case of cancer of the liver, Claxton, 424; on the treatment of diabetes, Dujardin-Beaumont, 457; malignant growths of the stomach and ovaries, Eskridge, J. T., 470; phthisis with absence of parietal pericardium and malposition of liver, Hughes, W. E., 472, 481; abdominal tumors in children, Whittier, E. N., 505; cylindrical-celled epithelioma of caecum, Hughes, W. E., 541; enteric paraplegia, Barthelme, R., 562; large intestines from two cases of chronic dysentery, one of them showing pseudo-polypl, Musser, J. H., 671; probable progressive hemorrhage into the bowel depending on general disorganization of the blood, Hodges, R. M., 608.
- Diphtheria.** Putnam, C. P., 10; cases of nasal diphtheria, Bush, J. F., and Stedman, G., 61.
- Diplomas.** Medical diplomas in Massachusetts, 40.
- Disinfectants,** note on, Buck, W. E., 528.
- Dispensary,** Boston, 381; new building of the Boston Dispensary, 525.
- Dixon, R. B.** Case of "cancer-drawing," 70; a new decapitating instrument, 239.
- Dizziness.** The sense of dizziness in deaf-mutes, James, 356.
- Draper, F. W.** On medical evidence and medical witnesses, 73, 97; absence of water from the stomach after immersion of a corpse, 255; two cases of typhoid fever in which kairin was given, 417, 420; on sudden death from the entrance of air into the uterine veins, 516.
- Dresses, ladies',** 381.
- Drowning.** Absence of water from the stomach after immersion of a corpse, Draper, F. W., 255.
- Drugs.** An amendment to the Massachusetts act to prevent adulteration of food and drugs, 66; report upon the adulteration of food and drugs, Davenport, B. F., 586.
- Duhning (Philadelphia).** The value of a lotion of sulphide of zinc in the treatment of lupus erythematosus, 254; a case of alnum with microscopic examination, 254.
- Dujardin-Beaumont** on the treatment of diabetes, 457, 481; some points regarding the use of bromides in epilepsy, 261.
- Dulles, C. W.** Specimen of very large ulcer of the stomach with unusual features, 423.
- Dunglison, R. J., and Marcy, H. O.** Report on laws regulating the practice of medicine in the United States and Canada, 390.
- Dwight, T.** Recent progress in anatomy, 225; a new demonstration of the cavities of the mouth, nose, and pharynx, 244, 255.
- Dyer, E.** A new perimeter, 300.
- Dysmenorrhoea.** Palmer, C. D., 308; the natural history of dysmenorrhoea, Williams, J., 453.
- Dyspepsia.** Peptonized milk as a curative agent in acute dyspepsia, Brannan, J. W., 54; the treatment of atonic dyspepsia, Fothergill, J. M., 236.
- Ear.** The neglect of ear symptoms in the diagnosis of diseases of the nervous system, Walton, G. L., 418; tinnitus aurium and vertigo as symptoms of lithemia, Lyman, G. H., 553, 555.
- Eclampsia.** The behavior of the uterus in puerperal eclampsia as observed in two cases, Hleka, B., 166.
- Eczema.** Was it a coincidence? 332.
- Eddison.** Opening the chest in emphysema, 332.
- Editorials.** Some medical aspects of the time of the Stuarts, 17, 39; the Boston Lunatic Asylum, forty-fourth annual report of the superintendent, 18; medical diplomas in Massachusetts, 40; the medical department of the British army in the Egyptian expedition, 65; an amendment to the Massachusetts act to prevent the adulteration of food and drugs, 66; the British army hospital service inquiry committee, 89; sanitation at Newport, 91; the Parkman professorship of anatomy in the Harvard Medical School, 91; telegraphy and health, 92; Professor Semmola on the pathogeny of Bright's disease, 113; the fine art of substitution, 114; epidemic cholera, 137; vital statistics of Providence, 137; Annual Report of the Boston Board of Health for the year 1882-1883, 160; Boston City Hospital, Nineteenth Annual Report, 161; Charity Hospital, New York, 182; fifty-first annual meeting of the British Medical Association, 183; tuberculous a century ago, 133; collective investigation, 206; "Thrift, thrift, Horatio," 206; a report on the communicability of phthisis, 207; medical men

- and the "classical fetich," 232; the study of medicine in Italy, 234; acute pneumonia, a preliminary report of the collective investigation committee, 253; the Adams Nervine Asylum, 253; the corners must go, 250; New York's water supply, 231; societies for the propagation of cremation and their hobby, 803; ambulance service, 377; the physiology of thermal sensations, 329; the tyranny of offensive trades, 329; copper as a prophylactic against cholera, typhoid fever, etc., 390; the New York Academy of Medicine and the Code, 350; prescription writing, 351; the Index Catalogue, No. IV, 352; the dedication of the new Harvard Medical School, 376; the Waltham murders in England, conviction of an insane criminal, 376; a French surgeon's impressions of the United States, 377; railway spine, 400; the conversion of malignant tumors into innocent growths, and the advantages of incandescent instruments, 400; Alaska from a medical point of view, 445; the medical treatment of insanity, 449; the medical teaching of the future in Boston and at the Harvard Medical School; the State Almshouse at Tewksbury, 423; localization of cerebral functions, 473; the cholera germ, 474; "regulars" and "irregulars" of the daily press, 475; the removal of the remains of William Harvey, 475; supplement, containing the Report and Papers on Public Health, to the fourth Annual Report of the State Board of Health, Lunacy, and Charity of Massachusetts, 1833, 497; registration report of Massachusetts for the year 1882, 498; the regulation of immigration, 521; diet in diabetes, 522; judicial murders, 522; intercollegiate foot-ball, 545; annual report of the surgeon-general United States army, 1833, 546; the report of the United States Marine Hospital Service, 546; the prosecution of manufacturers of adulterated drugs, 573; the markings of electricity, 574; insanity and murder: two trials, 593; the Index Medicus again, 594; annus medicus, 614.
- Education.** Graduates from the Harvard Medical School, 21; medical diplomas in Massachusetts, 40; medical men and the "classical fetich," 232; the study of medicine in Italy, 234; the School of Veterinary Medicine of Harvard University, Wilmington, C. F., 241; education in the medical profession, Clark, F. C., 261; changes in the system of medical education, Whittier, E. N., 239; the new century and the new building of the Medical School of Harvard University, Holmes, O. W., 361; the medical education of the future in Boston and at the Harvard Medical School, 426.
- Egyptian Expedition.** The medical department of the British army in the Egyptian expedition, 65.
- Electricity.** The markings of electricity, 574.
- Elliot, C. W.** Address at Harvard Medical School, 403.
- Embryos.** Material wanted for embryological research, 406.
- Emmet, T. A.** A study of the etiology of perineal lacerations, with a new method for its proper repair, 344.
- Empyema.** An unfavorable case of empyema, Richardson, M. H., 8; a contribution to the treatment of empyema, Cabot, A. T., 145, 153.
- Engelman, G. J.** Ergot, the use and abuse of this dangerous drug, 324.
- Epidemic.** "Epidemic Appropriation," Marine Hospital Service, 588, 598; the appropriation to prevent the spread of epidemic disease, Banks, C. E., 622; epidemic influences, Janeway, E. G., 569; epidemic pneumonia, 621.
- Epilepsy.** Some points regarding the use of bromides in epilepsy, Dujardin-Beaumetz, 261.
- Epithelioma.** Probable epithelioma cured by astringent washes, Francis, S. W., 300.
- Ergot.** The use and abuse of ergot, Woods, G. L., 125; the use and abuse of this dangerous drug, Engelman, G. J., 324.
- Ernst, H. C.** A contribution to the study of the tubercle-bacillus, 100, 121.
- Erysipelas.** Cerebral erysipelas, Clarke, A. P., 123.
- Eschle.** Eserine in diarrhoea, 41.
- Eserine in Diarrhoea.** Eschle, 41.
- Esbridge, J. T.** Hematoma in the upper portion of the mediastinum, producing death by suffocation, 86; extreme mitral stenosis, death resulting in a few months from sequential lesions without general dropsy, 18; malignant growth of the stomach and ovaries, 470.
- Evidence.** On medical evidence and medical witnesses, Draper, F. W., 73, 87.
- Exstrophy of the bladder with congenital fissure of the female urethra,** Jenks, E. W., 304.
- Eye.** The quickest, surest, and most practical method of ascertaining defects in the chromatic sense, Jeffries, B. J., 83; phlyctenular disease of the eyes, Wadsworth, O. F., 104; annual meeting of the American Ophthalmological Society, 110; results of the examination of the refraction of four consecutive classes at Amherst College, Derby, H., 110; a new combination of instruments for use in the extraction of cataract, Murdoch, R., 110; tubercle of the iris, Schell, H. S., 111; treatment of detachment of the retina from serous effusion or retinal hemorrhage, Mittendorf, W. F., 111; ectopia lentis, Little, W. S., 111; the use of nitrous oxide gas for minor ophthalmic operations, Stevens, G. T., 111; the titration of the cortex, Theobald, S., 112; blepharoplasty by the English method (aloplastic), 112; a new perimetral, Dyer, E., 300; choroid disease with pigmented patches, Miller, H. G., 301; opacities of the cornea, Reynolds, D. S., 323; some cases of hysterical affection of vision, Wadsworth, O. F., 368; "Know Dr. Knapp," 380; recent progress in ophthalmology, Wadsworth, O. F.; two cases of hysterical affection of the vision, Wadsworth, O. F., 559.
- Farlow, J. W.** Two cases in practice: (I.) anomalous menstrual symptoms with atrophy of the uterus; (II.) menorrhagia and chronic dyspareunia of two years' standing, cured by dilatation of the cervix uteri, 293.
- Farnham, E.** The last Englishman of note to die of ague, 531.
- Femoral Hernia.** An interesting case of femoral hernia in an aged patient, Blackwood, W. R. D., 314.
- Feris, B.** The elastic respirator in the treatment of dyspnea in the emphysematous, 452.
- Fibromas of the vagina,** Caswell, E. T., 151.
- Fifield, W. C. B.** Cases in service of Dr. Fifield, Dr. E. H. Bradford supplying, 59.
- Fiske Fund Prize,** 48.
- Fissure of Anus.** Idiopathic fissure of the anus, Becker, A. R., 354.
- Flint, A.** Clinical lecture on organic disease of the heart, 169; clinical lecture; heart complication in acute articular rheumatism; a case of fatty liver in connection with ascites from hepatic cirrhosis; remarks on tapping in the latter condition, 409.
- Folsom, N.** The digestibility of lobsters, 331.
- Food.** An amendment to the Massachusetts act to prevent adulteration of food and drugs, 66; the fine art of substitution, 114; dietetics for the sick, Seltzer, O. M., 317; the digestibility of lobsters, Folsom, N., 331; report upon the adulteration of food and drugs, Davenport, B. F., 536.
- Foot-Ball.** Intercollegiate foot-ball, 545.
- Forster, E. J.** The "longings" of pregnancy, 536; a self-retaining Sim's speculum, 537.
- Fothergill, J. M.** The treatment of atonic dyspepsia, 236.
- Fox (New York).** Leprosy, 253.
- Fractures.** The treatment of compound fractures, Vance, A. M., 327.
- Francis, S. W.** Probable epithelioma cured by astringent washes, 300.
- Freeman.** The case of Freeman, the insane killer of his child, 593.
- French surgeon's impressions of the United States,** 377.
- Fusible Metal.** The use of fusible metal in making injections for corrosion anatomical preparations, Mixter, J. S., 156.
- Garland, G. M.** Case of pemphigus pruriginosus, 151; tinea medio-cancellata, 393; theories regarding the mechanism of the inorganic cardiac murmurs, 25, 31.
- Gay, G. W.** The management of patients during capital operations, 156; letter from Liverpool, 184, 341.
- General Diseases.** Diphtheria, Putnam, O. P., 10; the relation between rubella and morbilli, Kassowitz, 94; cerebral erysipelas, Clarke, A. P., 123; epidemic cholera, 137; tuberculosis a century ago, 183; a report on the communicability of phthisis, 207; rheumatism in the horse, treatment by salicylate of soda, Abbot, S. L., 209; the change of medical opinion in regard to the cause and recent extension of malaria, Russell, C. P., 211; consumption in New England, Hurd, E. P., 265; rickets and congenital syphilis, Post, A., 325; copper as a prophylactic against cholera, typhoid fever, etc., 390; the last Englishman of note to die of ague, Farnham, E., 531; extirpation of the cancerous uterus, Jackson, R., 305; the conversion of malignant tumors into innocent growths, and the advantages of incandescent instruments, 400; case of cancer of the liver, Claxton, 424; the treatment of measles, Maclean, D., 454; recurrent scirrhus of the male breast, De Schweinitz, 471; phthisis with absence of pericardial pericardium and malposition of liver, Hughes, W. E., 472; the cholera germ, 474; a case of malignant disease of the uterus, Boardman, W. E., 493, 494; typhoid fever in New York, 517; can cancer of the penis be acquired by inoculation from cancer of the os uteri, Mundé, P. F., 527; case of sarcoma occupying the anterior mediastinum, Bruen, E. T., 542; a case of carcinomatous sarcoma of the left testicle, MacConnell, J. G., 572; syphilis of the brain and membranes, Wood, H. C., 577; a case illustrating one of the later lesions of syphilis, Grandin, E. G., 592; general tuberculosis as one of the sequelae of typhoid fever, Lyman, G. H., 607, 609.
- Generative System.** Some of the causes of sterility and their treatment, Thomas, T. G., 49; recent progress in gynecology, Davenport, F. H., 55; specimen of ovaries and uterus amputated at the cervix, Blodgett, A. N., 83; fibroma of the vagina, Caswell, E. T., 151; phymatous, Yarrow, H. C., 189; clinical report on cases of lacerated cervix, Warren, J. W., 197, 223; the treatment and curability of chronic uterine catarrh, Mundé, P. F., 238; chronic starvation and "delicate" females, Howitt, G., 285; two cases in practice: (I.) anomalous menstrual symptoms with atrophy of the uterus; (II.) menorrhagia and chronic dyspareunia of two years' standing cured by dilatation of the cervix uteri, Farlow, J. W., 293; superinvolution of the uterus, Johnson, J. T., 301; hot water in secondary hemorrhage after pelvic operations, Smith, A. H., 301; dysmenorrhoea, Palmer, C. D., 303; Annual Address American Gynecological Society, Kimball, G., 304; a rare form of abdominal tumor, Reamy, T. 304; a study of the etiology of perineal lacerations with a new method for its proper repair, Emmet, T. A., 344; accidental puncture of the uterus in laparotomy, Lee, C. C., 305; extirpation of the cancerous uterus, Jackson, R., 305; the treatment of pelvic peritonitis, Goodell, 310; menstruation after extirpation of the ovaries, Campbell, H. F., 320; remarks on chronic abscess of the pelvis, Byford, W. H., 323; ergot, the use and abuse of this dangerous drug, Engelman, G. J., 324; pseudo-membranous enteritis, Boardman, W. E., 374; nineteen cases of urethral stricture treated by internal urethrotomy, Tilden, G. H., and Watson, F. S., 385, 397; a case of two-horned uterus (uterus bicornis), Homans, J., 493, 416; the natural history of dysmenorrhoea, Williams, J., 453; diagnostic value of uterine hemorrhage after the menopause, Thomas, T. G., 454; malignant growths of the stomach and ovaries, Esbridge, J. T., 470; a case of malignant disease of the uterus, Boardman, W. E., 493, 494; can cancer of the penis be acquired by inoculation from cancer of the os uteri, Mundé, P. F., 527; a pediculated tumor of the anterior lip of the cervix uteri, Williams, E. T., 532; a case of carcinomatous sarcoma of the left testicle, MacConnell, J. G., 572; a case illustrating one of the later lesions of syphilis, Grandin, E. G., 592.
- Gilbert, D. D.** A modified urethral steel, 82; a case of tubal gestation with rupture and sudden death, 530, 535.
- Giovanni.** Observations on the therapeutic results of hypnotism, 524.
- Griffin, R. M.** Carcinoma (scirrhus) of the breast, 35.
- Glycogen.** Warren, J. W., 171.
- Goldsmith, W. B.** The early symptoms of general paralysis of the insane, 175.
- Goodell.** The treatment of pelvic peritonitis, 310.
- Gout.** Tinnitus aurium and vertigo as symptoms of lithemia, Lyman, G. H., 553, 555; recent views respecting the diagnosis and treatment of lithemia, Putnam, J. J., 556, 555.
- Graham (Toronto).** General exfoliative dermatitis, 252; lymphangioma cutis, 255.
- Grandin, E. H.** A case exemplifying one of the later lesions of syphilis, with remarks, 592.
- Greene, J. S.** Neurasthenia: Its causes and its home treatment, 75.
- Gruening, E.** Blepharoplasty by the English method (aloplastic), 112.
- Guaymas.** Yellow fever at Guaymas, 810.
- Hæmatoma in the upper portion of the mediastinum, producing death by suffocation,** Esbridge, J. T., 86.
- Hæmorrhage.** Controlling hæmorrhage in amputation at the hip-joint, Lloyd, J., 262; hot water in secondary hæmorrhage after pelvic operations, Smith, A. H., 303.
- Hall, J. N., M. D. (Harv.)** Voluntary dislocation of the hip-joint, 622.
- Hardaway.** A peculiar papillary disease of the skin, 254.
- Hare, C. L.** Good remedies out of fashion, 183.
- Harmon, S. T.** Placenta prævia with chronic Bright's disease, 373.
- Harrington, C.** A new and simple method of determining the percentage of fat in milk, 157.
- Harrison, E.** On some recent advances in the surgery of the urinary organs, 117.
- Hartwell, B. H.** Minor injuries of the spinal cord, 143.
- Harvard University.** Graduates from the Harvard Medical School, 21; the Parkman professorship of anatomy in the Harvard Medical School, 94; the School of Veterinary Medicine of Harvard University, Wilmington, C. F., 241; the new century and the new building of the Medical School of Harvard University, Holmes, O. W., 361; the dedication of the new

- Harvard Medical School, 876; the celebration of the one hundredth anniversary of the Harvard Medical School, and the dedication of its new building, 408; the medical teaching of the future in Boston and at the Harvard Medical School, 426.
- Harvey, W.** Removal of the remains of William Harvey, 475.
- Hawaiian Islands.** Letter from Honolulu, Hawaiian Islands, Heffenger, A. C., 44.
- Hay, T.** Iodoform for fissure of the anus, 211.
- Haynes, T.** Surgical treatment of hopeless cases of masturbation and nocturnal emissions, 180.
- Heart.** Organic disease of the heart, Flint, A., 169.
- Heffenger, A. C.** Letter from Honolulu, Hawaiian Islands, 44; malaria, 354.
- Hepatitis.** A case of suppurative hepatitis due to a pin in the vermiform appendix, Church, M. D., 269.
- Hermaphroditism.** Hermaphroditismus spurius masculinus bovis, Billings, F. S., 85; a case of hermaphroditism, Minot, F., 494.
- Hernia.** An interesting case of femoral hernia in an aged patient, Blackwood, W. R. D., 344.
- Hershey, G. D.** Pancoast's black iron-dyed surgical silk, 299.
- Hewitt, G.** Chronic starvation and "delicate" females, 285.
- Hicks, B.** On the behavior of the uterus in puerperal eclampsia as observed in two cases, 166.
- Hills, W. B.** Recent progress in medical chemistry, 130.
- Hip.** Congenital dislocation of the hip, Post, A., 193, 201; hip-joint, voluntary dislocation of the, 622.
- Hodges, R. M.** Probable progressive hæmorrhage into the bowel, depending on general disorganization of the blood, 608.
- Holmes, O. W.** The new century and the new building of the Medical School of Harvard University, 361; presentation of a portrait of Professor Holmes, 404.
- Holt, A. F.** A case of sudden death due to hæmorrhage from the hepatic vein, 584, 587.
- Holt, L. E.** A successful case of tetanus neonatorum treated with bromide of potassium, 370.
- Homans, J.** A case of two-horned uterus (uterus bicornis), 438, 446; myxo-sarcoma of the left kidney, 567.
- Honolulu.** Letter from Honolulu, H. I., Heffenger, A. C., 44.
- Hooper, R. M.** Probable progressive hæmorrhage into the bowel depending on general disorganization of the blood, 608.
- Horse.** Rheumatism in the horse; treatment by salicylate of soda, Abbot, S. L., 209; scarlet fever in horses, Peters, J. C., 422.
- Hosmer, A.** Case of retained placenta, 536; foetal calf with a fifth limb growing from its back, 536.
- Hospital Duty.** past and present, 621.
- Hospitals for the insane.** Channing, W., 462.
- Hot Bath in asphyxia.** 280.
- Hour-glass contraction of the uterus.** Stedman, J., 374.
- Howe, O. T.** A strange case, 433.
- Hughes, W. E.** Phthisis with absence of parietal pericardium and malposition of liver, 472; cylindrical-celled epithelioma of cæcum, 541.
- Hurd, E. P.** Apoplexy of the cerebellum, 195; consumption in New England, 266.
- Hutchinson, J.** The significance of appearances of the tongue, 357.
- Hyde.** A study of the coincidence of syphilitic and non-syphilitic affections of the skin, 254.
- Hygiene, Health, and Boards of Health.** Sanitary report of the Connecticut State Board of Health, 71; sanitation at Newport, 91; telegraphy and health, 92; New York's water supply, 231; the tyranny of offensive trades, 329; the hygiene of the lying-in room, Minot, F., 343; recent progress in public hygiene and State medicine, Abbott, S. W., 442; report and papers on public health, Massachusetts State Board of Health, Lunacy, and Charity, 497; a meeting of State Boards of Health at Detroit, November, 1883, 542; sewer gases, Smith, S., 570; dangers to the public health from the erection of high apartment houses, Vanderpoel, 570.
- Hygiene of the lying-in room.** Minot, F., 343.
- Hyperidrosis Manuum.** Smith, H. A., 282.
- Hypnotism.** Observations on the therapeutic results of hypnotism, Giovanni, 524.
- Hysteria.** Some cases of hysterical affection of vision, Wadsworth, O. F., 368.
- Immigration.** The regulation of immigration, 521.
- Index Catalogue.** No. IV., 352.
- Index Medicus.** 594.
- Inebriates.** A neglected field of medical supervision, Shute, C. B., 485, 509.
- Infanticide.** Some remarks upon infanticide, with report of a case of infanticide by drowning, Pinkham, J. G., 411.
- Ingalls, W.** Division of the internal jugular vein, 230.
- Instruments and Apparatus.** Insufflators, De Blois, T. A., 13; a handy internal angular splint, Trumbull, J., 15; a modified urethral steel sound, Gilbert, D. D., 82; a new combination of instruments for use in the extraction of cataract, Murdoch, H., 110; new instrument for removing foreign bodies from the bladder, Merrill, J. W., Jr., 178; a new decapitating instrument, Dixon, R. B., 299; Pancoast's black iron-dyed surgical silk, 299; a new perimeter, Dyer, E., 300; the use of the roller bandage, Link, J. E., 327; club-foot apparatus in cases of contracture, Sayre, L. A., 334; the rapid evaporation of stone from the bladder after crushing — with presentation of a new and simplified evacuator, Otis, F. N., 467; a self-retaining Sims's speculum, Forster, E. J., 537.
- Insufflators.** De Blois, T. A., 13.
- Iodoform absorption and insanity.** Liebmann, G., 280.
- Italy.** The study of medicine in Italy, 234.
- Jackson, R.** Extirpation of the cancerous uterus, 305.
- James.** The sense of dizziness in deaf-mutes, 350.
- James, A.** Ankle clonus in relation to the height of the individual, 94.
- Janeway, E. G.** Mortality tables and epidemic influences, 569.
- Japan.** Use of the moxa in Japan, Kneeland, S., 211.
- Jeffries, B. J.** The quickest, surest, and most practical method of ascertaining defects in the chromatic sense, 83.
- Jenke, K. W.** Congenital fissure of the female urethra with exstrophy of the bladder, 304.
- Johnson, J. T.** Superinvolution of the uterus, 301.
- Jones, C. M.** Three obstetrical cases complicated I. by albuminuria; II. by erysipelas; III. by eclampsia and septicæmia, 293.
- Jurisprudence.** On medical evidence and medical witnesses, Draper, F. W., 78, 97; death from carbolic acid, Batchelder, D. H., 251; absence of water from the stomach after immersion of a corpse, Draper, F. W., 255; Walthamstow murders in England; conviction of an insane criminal, 376; report of a case of murder, Paine, A. E., 389; report on laws regulating the practice of medicine in the United States and Canada, 390; some remarks upon infanticide, with report of a case of infanticide by drowning, Pinkham, J. G., 411; a strange case, Howe, O. T., 433; judicial murders, 522; report of the executive council of the Massachusetts Medico-Legal Society on the work of the medical examiners for the year 1882, 439; medico-legal notes; hypertrophy of the prostate from a forensic point of view, 548; insanity and murder: two trials, 538.
- Kairin** as an antipyretic in typhoid fever, Shattuck, G. B., 415; two cases of typhoid fever in which kairin was given, Draper, F. W., 417, 420.
- Kassowitz.** The relation between rubella and morbilli, 94.
- Keating, J. M.** Some observations on the salivary digestion of starch by infants, 31.
- Key, A. T.** A new interpretation of Flint's mitral direct or presystolic murmur without mitral lesions, 30; the negative arterial pulse, 340.
- Kidney.** Notes of a peculiar case in which the autopsy showed congenital absence of the left kidney, Church, M. D., 588.
- Kimball, G.** Annual Address, American Gynecological Society, 304.
- Kingman, R. A.** Prague, 46.
- Knapp, H.** A note from Dr. Knapp, 430.
- Kneeland, S.** Use of the moxa in Japan, 211.
- Knight, F. I.** Report on progress in the treatment of diseases of the throat, 151, 179.
- "Know Dr. Knapp,"** 380.
- Ladies' Dresses.** 389.
- Laparotomy.** Accidental puncture of the uterus in laparotomy, Lee, C. C., 306.
- Lard.** Medical expert testimony in the Chicago lard testimony, 68.
- Laurison (Philadelphia).** Bacillus tuberculosis, 64.
- Lead.** Paralysis of lower extremities from lead; rapid recovery under iodide of potassium, Minot, F., 155; on certain unrecognized forms of lead-poisoning; and on the possibility of mistaking blamuth for lead in urine analysis, Putnam, J. J., 315; lead-poisoning from canned food, Magruder, 332.
- Lee, C. C.** Accidental puncture of the uterus in laparotomy, 306.
- Levis, R. J.** Surgical expedients in emergencies, 213.
- Liebmann, G.** Iodoform absorption and insanity, 280.
- Ligamentum Patellæ.** Rupture of the ligamentum patellæ, Richardson, M. H., 229.
- Link, J. E.** The use of the roller bandage, 328.
- Lister** on fracture of the patella, Manton, W. P., 478.
- Lithæmia.** Tinnitus aurium and vertigo as prominent symptoms of lithæmia, Lyman, G. H., 553, 555; recent views respecting the diagnosis and treatment of lithæmia, Putnam, J. J., 556, 556.
- Little, W. S.** Ectopia lentis, 111.
- Liver.** Shrinkage in cirrhosis of the liver, Seymour, W. W., 259; a case of sudden death due to hæmorrhage from the hepatic vein, Holt, A. F., 584, 587.
- Liverpool.** Letter from Liverpool, Gay, G. W., 164.
- Lloyd, J.** Controlling hæmorrhage in amputation at the hip-joint, 262.
- LOBSTERS.** The digestibility of lobsters, Folsom, N., 331.
- Localization of cerebral functions.** 473.
- London.** Letter from London, Manton, W. P., 478.
- "Longings"** of pregnancy, Forster, E. J., 536.
- Lörl, E.** Morbid changes of the throat, larynx, and air-passages in some acute infectious diseases, 287.
- Lyman, G. H.** Tinnitus aurium and vertigo as prominent symptoms of lithæmia, 553, 555; general tuberculosis as one of the sequelæ of typhoid fever, 607, 609.
- Lynch, J. S.** Tricuspid regurgitation, 237.
- MacConnell, W. G.** A case of carcinomatous sarcoma of the left testicle, 572.
- Macdonald, A. D.** Position in labor, 233.
- Maclean, D.** The treatment of measles, 454.
- Maine.** Letter from Maine, 43.
- Malaria.** The change of opinion in regard to the cause and recent extension of malaria, Russel, C. P., 211; the last Englishman of note to die of ague, Farnham, E., 331; malaria, Heffenger, A. C., 354.
- Mammary Gland.** chronic abscess of, Crandall, C. R., 224.
- Management of patients during capital operations.** Gay, G. W., 164, 341.
- Manton, W. P.** Letter from London, 478.
- Maories.** Parturition among the Maories, 356.
- Marcy, H. O., and Dunglison, R. J.** Report on laws regulating the practice of medicine in the United States and Canada, 390.
- Marine Hospital Service.** The Report of the United States Marine-Hospital Service, 546; "epidemic appropriation," N***, 598; the appropriation to prevent the spread of epidemic disease, Banks, C. E., 621.
- Marriage of neurotic patients.** Savage, G. H., 141.
- Massachusetts.** An amendment to the Massachusetts act to prevent the adulteration of food and drugs, 66.
- Massage.** The risks of massage, Althaus, J., 279.
- Masturbation.** Surgical treatment of hopeless cases of masturbation and nocturnal emissions, Haynes, T., 180.
- Materia Medica and Therapeutics.** Sea-sickness: its treatment by bromide of sodium, Walton, G. L., 4, 137; eserin in diarrhoea, Esche, G. L.; salicine in rheumatism, 120; the use and abuse of ergot, Woods, G. L., 125; treatment of double pneumonia by inhalation of oxygen, Bowditch, H. I., 156; good remedies out of fashion, Hare, C. L., 133; report on materia medica and pharmacy, Bolles, W. P., 193; use of the moxa in Japan, Kneeland, S., 211; iodoform for fissure of the anus, Hay, T., 211; some hints regarding the use of bromides in epilepsy, Dujardin-Beaume, 261; iron and arsenic in anemia and chlorosis, Willocks, 261; report on progress in therapeutics, Williams, F. H., 270, 296; the risks of massage, Althaus, J., 279; bromide of arsenic in diabetes mellitus, 284; ergot, the use and abuse of this dangerous drug, Engelmann, G. J., 324; a successful case of tetanus neonatorum treated with bromide of potassium, Holt, L. E., 370; corrosive sublimate in midwifery practice, Tardier, 332; kairin as an antipyretic in typhoid fever, Shattuck, G. B., 415; kairin as an antipyretic in typhoid fever, Draper, F. W., 417, 420; naphthol: its medicinal uses and value, Shoemaker, J. V., 440; the administration of quinine, Young, D., 454.
- Measles.** The relation between rubella and morbilli, Kassowitz, 94; the treatment of measles, Maclean, D., 454.

- Medical Examiners.** The coroner must go, 280; medical examiners, 800; medical examiners in Rhode Island, 811.
- Medical Register** for New England, Brown, F. H., 549.
- Menstruation** after extirpation of the ovaries, Campbell, H. F., 820.
- Merrill, J. W., Jr.** The removal of foreign bodies from the human bladder by a new instrument, 178.
- Milk.** A new and simple method of determining the percentage of fat in milk, Harrington, C., 157; enormous milk flow, Remy, C., 528.
- Miller, H. G.** Choroid disease with pigmented patches, 800.
- Mind.** The early symptoms of general paralysis of the insane, Goldsmith, W. B., 175; iodoforn absorption and insanity, Liebmann, G., 280; science and psychism, 882; Walthamstow murders in England; conviction of an insane criminal, 376; mania; ruptured cervix uteri, Whitney, W. F., 447; the medical treatment of insanity, 449; report on recent progress in the construction of insane hospitals and management of the insane, Channing, W., 462; insanity and murder; two trials, 593.
- Minot, F.** Obscure case of ascites and anasarca, 154; paralysis of lower extremities from lead; rapid recovery under iodide of potassium, 155; the hygiene of the lying-in room, 848, 872; a case of hermaphroditism, 494; a case of death from heart clot following etherization, 560, 568.
- Mittendorf, W. F.** Treatment of detachment of the retina from serous effusion or retinal hemorrhage, 111.
- Mixer, J. S.** The use of fusible metal in making injections for corrosion anatomical preparations, 168.
- Monsters.** Hermaphroditismus spurius masculinus bovis, Billings, F. S., 85; the treatment of monstrosities, Wey, W. C., 858; a case of hermaphroditism, Minot, F., 494; foetal calf with a fifth limb growing from its back, Hosmer, A., 536.
- Montgomery.** The case of Montgomery, the murderer of his child, 594.
- Morrow (New York).** Pathogenesis of drug eruptions, 258.
- Mortality Tables** and epidemic influences, Janeway, E. G., 569.
- Moxa.** Use of the moxa in Japan, Kneeland, S., 211.
- Mudd, H. H.** Stone in the bladder, 828.
- Mundé, P. F.** "Immediate and forcible removal of the placenta after abortions," 165; the treatment and curability of chronic uterine catarrh, 288; can cancer of the penis be acquired by inoculation from cancer of the cervix uteri, 527.
- Murdoch, R.** A new combination of instruments for use in the extraction of cataract, 110.
- Murmurs.** Theories regarding the mechanism of the inorganic cardiac murmurs, Garland, G. M., 25, 84; the diagnosis of the so-called "functional murmurs," 28, 84; a new interpretation of Flint's mitral direct or presystolic murmur without mitral lesions, Keyt, A. T., 80.
- Muscles.** Cataleptic state of the muscles, Brown-Sequard, 856.
- Mushrooms.** Poisonous mushrooms, Palmer, J. A., 275.
- Musser, J. H.** Carcinoma (scirrhus) of the rectum, 85; sarcoma of the bladder, 83; kidneys and heart from a case of chronic kidney disease; extreme uræmic dyspnea; marked edema; relief to both by acupuncture; incipient neuritis, 62; aortic valvular disease due to the combined action of strain and rheumatism; excessive dilated hypertrophy, 68; a specimen of renal calculus, oxalate of lime, 96; large intestines from two cases of chronic dysentery, one of them showing pseudo-polypi, 571.
- Nancrede (Philadelphia).** Congenital fatty tumor beneath occipito-frontal muscle, 87; adenomatous growth, apparently recurrent, in reality an outlying portion of the mamma, not removed at a previous operation, 87.
- Naphthol:** Its medicinal uses and value, Shoemaker, J. V., 440.
- Navy.** Surgical appliances for disabled soldiers and sailors, Crane, O. H., 236.
- Nervous System.** Tumor of the sciatic nerve, Schweinitz, 68; neurasthenia: its causes and its home treatment, Greene, J. S., 75; ankle clonus in relation to the height of the individual, James, A., 94; cerebral erysipelas, Clarke, A. P., 128; the marriage of neurotic patients, Savage, G. H., 141; minor injuries of the spinal cord, Hartwell, B. H., 148; paralysis of lower extremities from lead; rapid recovery under iodide of potassium, Minot, F., 155; the early symptoms of general paralysis of the insane, Goldsmith, W. B., 175; cerebral tumor mistaken for hysteria, Bruce, 209; on some local nervous manifestations, Charcot, 212; recent investigations into the pathology of the so-called concussion of the spine, Putnam, J. J., 217; treatment of whooping-cough, Archambault, 238; recent progress in nervous diseases, Webber, S. G., 245; possible cerebral origin of the symptoms usually classed as "railway spine," Walton, G. L., 387; the sense of dizziness in deaf-mutes, James, 350; cataleptic state of the muscles, Brown-Sequard, 358; some cases of hysterical affection of vision, Wadsworth, O. F., 368; a successful case of tetanus neonatorum treated with bromide of potassium, Holt, L. E., 370; railway spine, 400; the neglect of ear symptoms in the diagnosis of diseases of the nervous system, Walton, G. L., 418; localization of cerebral functions, 478; observations on the therapeutic results of hypnotism, Giovanni, 524; spinal injury and money, Whitney, J. O., 527; two cases of hysterical affection of the vision, Wadsworth, O. F., 539; tinnitus aurium and vertigo as prominent symptoms of lithæmia, Lyman, G. H., 553; enteric paraplegia, Bartholow, R., 562; cerebral exhaustion, Corning, J. L., 570; spinal irritation; probable cerebral origin of the symptoms sometimes classed under this head, Walton, G. L., 601; syphilis of the brain and membranes, Wood, H. C., 577; two cases of paraphasia, one with autopsy, Webber, S. G., 581, 587.
- Neurasthenia:** Its causes and its home treatment, Greene, J. S., 75.
- New England.** Consumption in New England, Hurd, E. F., 265; New England Medical Register, Brown, F. H., 549.
- Newport.** Letter from Newport, 69; sanitation at Newport, 91.
- Newton, R. C.** A case of cold abscess, 246.
- New York.** Charity Hospital, 182; New York's water supply, 281; typhoid fever in New York, Delafeld, F., 517.
- Nocturnal Emissions.** Surgical treatment of hopeless cases of masturbation and nocturnal emissions, Haynes, T., 130.
- Nurses.** The training of nurses, Rowe, G. H. M., 1, 6; trained nurses, a criticism, Otis, E. O., 429.
- O'Leary.** Reproduction of first phalanx of index finger, 800.
- Orthopraxy.** Congenital dislocation of the hip, Post, A., 198, 201; contraction of the knee joint treated by splints, Burrell, H. L., and Watson, F. S., 302; the effect of recumbency on the length of the spine, Bradford, E. H., 245; a physiological method of treating caries of the dorsal vertebra, Stillman, C. F., 273; severe cases of club-foot, Bradford, E. H., 278; report on progress in surgery of deformities and diseases of joints, Bradford, E. H., 341.
- Osteo-Malacia.** A case of osteo-malacia with autopsy, Stone, L. R., 220, 220.
- Otis, E. O.** Trained nurses; a criticism, 429.
- Otis, F. N.** The rapid evacuation of stone from the bladder after crushing, with presentation of a new and simplified evacuator, 467.
- Otis, J. W.** Hemorrhage following tonsillotomy, 227.
- Oxygen.** Treatment of double pneumonia by inhalation of oxygen, Bowditch, H. I., 156.
- Paine, A. E.** Report of a case of murder, 389.
- Palmer, C. D.** Dysmenorrhœa, 808.
- Palmer, J. A.** Poisonous mushrooms, 275.
- Pancoat's** black iron-dyed surgical silk, Hersey, G. D., 299.
- Paraphasia.** Two cases of paraphasia, Webber, S. G., 581, 587.
- Parasites.** The diagnosis of tenias intestinales, 119; tenia medio-cancellata, Garland, G. M., 898.
- Parkman** professorship of anatomy in the Harvard Medical School, 91.
- Patella.** Mr. Lister on fracture of the patella, Manton, W. P., 478.
- Pathology.** Recent progress in pathology and pathological anatomy, Whitney, W. F., 491, 511.
- Pemphigus Fruriginosus.** Garland, G. M., 181.
- Peptonized Milk** as a curative agent in acute dyspepsia, Brannan, J. W., 54.
- Perinæum.** A study of the etiology of perinæal laceration with a new method for its proper repair, Emmet, T. A., 304.
- Peritonitis.** The treatment of pelvic peritonitis, Goodell, 810.
- Perry, T. W.** Exfoliative dermatitis, 800.
- Peters, John C.** Scarlet fever in horses, 422.
- Phalanx of Index Finger,** reproduction of, O'Leary, 800.
- Pharmacy.** Report on materia medica and pharmacy, Boiles, W. P., 186.
- Phthisis.** A report on the communicability of phthisis, 207; arrested phthisis, Bowditch, H. I., 569.
- Physiology.** Glykogen, Warren, J. W., 171; reproduction of first phalanx of index finger, O'Leary, 800; the physiology of thermal sensations, 829; a seventh sense, Thomson, W., 452; localization of cerebral functions, 478.
- Physometra.** Yarrow, H. C., 189.
- Piffard (New York).** Treatment of acne, 251.
- Pinkham, J. W.** Some remarks upon infanticide, with report of a case of infanticide by drowning, 411.
- Placenta.** "Immediate and forcible removal of the placenta after abortions," Mundé, P. F., 165; Sweringen, H. V., 236.
- Placenta Prævia** with chronic Bright's disease, Harmon, S. T., 378.
- Plastic Operations.** Plastic operation for burn, Porter, C. B., 85.
- Pneumonia.** A case of croupous pneumonia occurring in a child with serious mitral disease; recovery, Cutler, E. G., 78, 84; treatment of double pneumonia by inhalation of oxygen, Bowditch, H. I., 156; acute pneumonia; a preliminary report of the collective investigation committee, 256; epidemic pneumonia, 621.
- Poisons.** A case of laudanum-poisoning in an infant one day old, Stedman, G., 50, 60; prolonged suspension of vitality due to atropia injected hypodermically, Alexander, 141; paralysis of lower extremities from lead; rapid recovery under iodide of potassium, Minot, F., 155; death from carbolic acid, Batehelder, D. H., 251; poisonous mushrooms, Palmer, J. A., 275; on certain unrecognized forms of lead-poisoning, and on the possibility of mistaking bismuth for lead in urine analysis, Putnam, J. J., 815; lead-poisoning from canned food, Magruder, 838; a neglected field of medical supervision, Shute, C. B., 485, 509.
- Porter, C. B.** Plastic operation for burn, 85; old stricture, multiple abscess, perineal section, septicaemia, death, 609.
- Position in Labor.** Macdonald, A. D., 283.
- Post, A.** Congenital dislocation of the hip, 193, 201; rickets and congenital syphilis, 325.
- Post-Mortem Diagnosis.** Stedman, J., 185.
- Prague.** Letter from Prague, Kingman, R. A., 46.
- Pregnancy, Affections Connected With.** Report on obstetrics, Richardson, W. L., 82; two cases of abortion, Stedman, G., 50, 60; "immediate and forcible removal of the placenta after abortions," Mundé, P. F., 165; the responsibility of accoucheurs after infectious exposure, 166; on the behavior of the uterus in puerperal eclampsia as observed in two cases, Hicks, B., 186; clinical report on cases of lacerated cervix, Warren, J. W., 197, 223; case of labor; pyemia; recovery, Spear, D. D., 200; "the immediate and forcible removal of the placenta after abortions," Sweringen, H. V., 236; position in labor, Macdonald, A. D., 283; three obstetrical cases complicated I. by albuminuria; II. by erysipelas; III. by eclampsia and septicaemia, 293; a case of manual dilatation of the os uteri for the removal of a dead fetus, Worcester, A., 298; a new decapitating instrument, Dixon, R. B., 299; management of the third stage of labor, Anthony, W. E., 299; chloroform in labor, Woolen, G. V., 328; the hygiene of the lying-in room, Minot, F., 843, 872; parturition among the Maories, 356; placenta prævia with chronic Bright's disease, Harmon, S. T., 378; hour-glass contraction of the uterus, Stedman, J., 375; corrosive sublimate in midwifery practice, 383; mania; ruptured cervix uteri, Whitney, W. F., 447; on sudden death from the entrance of air into the uterine veins, Draper, F. W., 518; enormous milk-flow, Remy, C., 528; two cases of excessive vomiting of pregnancy, one fatal, Stedman, C. E., 548, 586; a case of tubal gestation, with rupture and sudden death, Gilbert, D. D., 530, 585; the "longings" of pregnancy, Foster, E. J., 536; case of retained placenta, Hosmer, A., 536; foetal calf with a fifth limb growing from its back, Hosmer, A., 536; two obstetric cases accompanied by unusual symptoms, Swift, J. B., 537; the prevention and treatment of puerperal septicaemia, Thomas, T. G., 589.
- Prescription Writing,** 551.
- Prices.** Fiske fund price, 48.
- Providence.** Vital statistics of Providence, 187.
- Psoriasis.** The treatment of psoriasis, Van Harlingen, A., 438.
- Pulse.** The negative arterial pulse, Keyt, A. T., 840.
- Purpura** from quinine, Wigglesworth, E., 587.
- Putnam, C. F.** Diphtheria, 10.
- Putnam, J. J.** Recent investigations into the pathology of so-called concussion of the spine, 217; on certain unrecognized forms of lead-poisoning, and on the possibility of mistaking bismuth for lead in urine analysis, 816; recent views respecting the diagnosis and treatment of lithæmia, 555, 555.
- Putrefaction.** A case of delayed putrefaction, Taylor, W. H., 451; "A case of delayed putrefaction," Clarke, H. B., 598.
- Quinine.** The administration of quinine, Young, D., 454; purpura from, Wigglesworth, E., 587.
- "Railway Spine."** Possible cerebral origin of the symptoms usually classed as "railway spine," Walton, G. L., 387; railway spine, 400.

- Randolph, N. A.** A note on the faeces of starch-fed infants, 52.
- Reamy, T.** A rare form of abdominal tumor, 304.
- Recent Progress.** Obstetrics, Richardson, W. L., 32; gynecology, Davenport, F. H., 55; children, Rotch, T. M., 79, 108; medical chemistry, Hills, W. B., 130; throat, Knight, F. I., 151, 179; materia medica anapharmacy, Bolles, W. P., 195; anatomy, Dwight, T., 225; nervous diseases, Webber, S. G., 248; surgery of deformities and diseases of joints, Bradford, E. H., 344; dermatology, Tilden, G. H., 393; physiologic chemistry, Warren, J. W., 413; public hygiene and State medicine, Abbott, S. W., 442; construction of insane hospitals and management of the insane, Channing, W., 461; pathology and pathological anatomy, Whitney, W. F., 491, 511; ophthalmology, Wadsworth, O. F., 533; report upon the adulteration of food and drugs, Davenport, B. F., 536; surgery, Cabot, A. T., 605.
- Registration.** Vital statistics of Providence, 137; registration of deaths, Turner, H. E., 301.
- "Regulars" and "Irregulars"** of the daily press, 475.
- Remy, C.** Enormous milk-flow, 528.
- Respiratory System.** An unfavorable case of empyema, Richardson, M. H., 8; a case of croupous pneumonia occurring in a child with serious mitral disease; recovery, Cutler, E. G., 73, 84; a contribution to the treatment of empyema, Cabot, A. T., 145, 153; easy method of posterior rhinoscopy, Walsam, W. J., 139; a report on the communicability of phthisis, 207; a new demonstration of the cavities of the mouth, nose, and pharynx, Dwight, T., 244, 255; the third tonsil and diphtheria, Blodgett, A. N., 255; acute pneumonia, a preliminary report of the collective investigation committee, 256; morbid changes of the throat, larynx, and air-passages in some acute infectious diseases, Lort, E., 287; pulmonary complications, erythema nodosum, Sée, G., 311; surgery of the lungs, Bull, 355; hot bath in asphyxia, 380; opening the chest in empyema, Edlison, 383; the elastic respirator in the treatment of dyspnoea in the emphysematous, Férís, B., 452; posterior nasal hypertrophy in situ, together with an ectostoma from the vomer, Seiler, 469; phthisis with absence of parietal pericardium and malposition of liver, Hughes, W. E., 472; arrested phthisis, Bowditch, H. I., 569.
- Reynolds, D. S.** Opacities of the cornea, 328.
- Rheumatism.** Salicine in rheumatism, 120; heart complication in acute articular rheumatism, Flint, A., 409.
- Rhinoscopy.** Easy method of posterior rhinoscopy, Walsam, W. J., 139.
- Rhode Island.** Surgical cases in the service of Drs. G. W. Carr and E. T. Caswell in Rhode Island Hospital, 133; medical examiners in Rhode Island, 311.
- Richardson, M. H.** An unfavorable case of empyema, 8; rupture of the ligamentum patellae, 229.
- Richardson, W. L.** Report on obstetrics, 32.
- Rickets and congenital syphilis,** Poet, A., 325.
- Roller Bandage.** Link, J. E., 323.
- Rotch, T. M.** Recent progress in diseases of children, 79, 108; a case of thrombosis of the straight cerebral sinus, 174.
- Rowe, G. H. M.** The training of nurses, 1, 6.
- Rubecula.** The relation between rubecula and morbilli, Kaseowitz, 94.
- Russell, C. P.** The change of medical opinion in regard to the cause and recent extension of malaria, 211.
- St. Louis.** Letter from St. Louis, Shapleigh, J. B., 93.
- St. Petersburg.** Letter from St. Petersburg, Amory, B., 596.
- Salicine in rheumatism,** 120.
- Sansom, A. E.** Preystolic murmurs, organic and inorganic, 1190.
- Santa Barbara.** The climate of Santa Barbara and the Northern Pacific Coast, 354.
- Savage, G. H.** Marriage of neurotic patients, 141.
- Sayre, L. A.** Club-foot apparatus in cases of contracture, 334.
- Scarlet Fever in horses,** Peters, J. C., 422.
- Schell, H. S.** Tubercle of the iris, 111.
- Schweinitz, G. De.** Tumor of the sciatic nerve, 63; sarcoma of the breast, 573.
- Sciatic Nerve.** Tumor of the sciatic nerve, Schweinitz, G. S.
- Science and psychism,** 332.
- Sea Bathing,** 70.
- Sea-Sickness:** Its treatment by bromide of sodium, Walton, G. L., 4, 137.
- Sée, G.** Pulmonary complications of erythema nodosum, 311.
- Seiler (Philadelphia).** Posterior nasal hypertrophy in situ, 469, 495.
- Seltzer, C. M.** Dietetics for the sick, 317.
- Hemimola (Naples).** Pathogeny of Bright's disease, 113.
- Septicæmia.** The prevention and treatment of puerperal septicæmia, Thomas, T. G., 589.
- Sewer Gases.** Smith, S., 570.
- Sexual Development.** Clinical lecture on failure of sexual development, Thomas, T. G., 313.
- Seymour, W. W.** Tumor of cerebellum, 200; shrinkage in cirrhosis of the liver, 259.
- Shapleigh, J. B.** Letter from St. Louis, 93.
- Shattuck, F. C.** The diagnosis of the so-called "functional murmurs," 23, 34.
- Shattuck, G. B.** Kalrin as an antipyretic in typhoid fever, 415.
- Sherwell (Brooklyn).** Paget's disease or malignant papillary dermatitis, 253; pseudo-porriasis and porriasis of the palm, 254.
- Shoemaker, J. V.** Naphthol: Its medicinal uses and value, 440.
- Shute, C. B.** A neglected field of medical supervision, 495, 509.
- Smith, A. H.** Hot water in secondary hemorrhage after pelvic operations, 303.

THE TRAINING OF NURSES.¹

BY G. H. M. ROWE, M. D.,

Superintendent and Resident Physician Boston City Hospital.

THE subject chosen for this reading is not strictly within the line of work to which this Society is devoted, that of clinical medicine, and I feel like apologizing for its introduction. The members of the Society are, however, aware that the superintendent of a large metropolitan hospital has little time for the conscientious observation of clinical cases. There are problems closely connected with the functions of his office which, by limitation, other members of the profession have less opportunity of studying. I have ventured to depart from the traditions by bringing forward the education of nurses, a subject which, both to physician and patient, is quite as important as drugs or food. I do this in order to make some statements about the present position of the subject in regard to hospital work, the profession, and the public.

It is only ten years since the first training school for nurses was organized in this country. They have passed the experimental stage, but are far from being on a basis that would be considered as eminently satisfactory, either as to organization, methods of work, or results, as shown in the work of graduates in private nursing.

Some of the methods are known to the profession, and in a limited way to the public, sufficiently to judge the system by its results. I forbear to detail the history of the "old system," so called, or to rehearse the causes that led to the establishment of the new. It must be remembered that until 1860 there was no opportunity in Europe or America for an enterprising woman of any social degree to systematically learn nursing unless she entered one of the religious sisterhoods, and the aim of most of these orders was a divided one, their own spiritual welfare and that of their patient.

The work of Pastor Fliehn, begun in 1836 at Kaiserswerth, in Germany, where Florence Nightingale obtained her training, should not be forgotten. This was a semi-religious order, the nurses becoming deaconesses for five years, most of them remaining in the order for life.

In 1860, by the energy of that rare and devoted woman, Florence Nightingale, there was opened at St. Thomas's Hospital in London the first organized training school of merit connected with any large hospital supported and managed by the laity.

This school is not only the pioneer of the modern training school, but is to the present time the model upon which nearly all are organized. The methods and maxims of this school are closely imitated by most others of any pretension or real worth, and its success and results have never been surpassed, perhaps not equaled.

In 1868 a special committee was appointed by the American Medical Association to consider what could be done to begin in this country the systematic training of nurses. Dr. S. D. Gross was chairman of that committee, and at the meeting the following year read a report, which may be found in the Transactions

for 1869. This report was forwarded to all State medical societies, but the endeavor to excite an interest in the subject received no active response.

For many years the Nurses' Society in Philadelphia (the work of the Friends) had been doing unostentatious and quiet work for the Lying-in Charity. The philanthropic pastor and superintendent of St. Luke's Hospital in New York (Dr. Muhlenberg) instituted, in 1845, a semi-religious order of sisters in the English Church. With his death the order waned, and no longer constitutes the nursing force of the hospital.

The success of the Nightingale School at St. Thomas's, and the organization of others abroad, on this plan, gradually attracted attention in the United States.

In 1873 there were opened three well-organized training schools, namely, the Bellevue, in New York, the Connecticut School, in New Haven, and the Massachusetts General Hospital School, in Boston. From this beginning, ten years ago, others have been established until there are now, according to the best information I can obtain, about sixteen schools of size and dignity. The varying conditions under which these schools were commenced led to a basis of organization that was not uniform. They are so different in kind and method as to practically affect their welfare both as to their workings and results, and to leave much room for discussion as to which is superior. I consider this point of sufficient importance to analyze more closely.

In brief there are two kinds of organizations. By one method friends of a given hospital, prominent citizens, the medical staff, and, usually and largely, influential women of social rank and strong personality, organize themselves into a corporation for the sole purpose of establishing a school for nurses. They obtain a charter enabling them to hold funds and property, organize into various committees, secure a superintendent of nurses as their executive officer and instructor, and obtain pupils for training. They enter into a compact with the trustees of a hospital to supply them with nurses, who take charge of the nursing of the patients, subject to the authority of the hospital, its management, and its regulations. In return the hospital remunerates the training school with payment of service, board of nurses, etc. The purpose of the training school is to educate nurses, thus furnishing a better nursing force to the hospital, and supplying trained nurses to the public. The object of the trustees of the hospital is the improved care of the sick.

By the second method the trustees or managing board of the hospital, with the same end in view, undertake to accomplish what in the first case was done under two organizations. It appoints a committee from its own board, whose special duty is to organize and regulate the workings of the school, with an advisory committee from the hospital staff. The school at once becomes an integral part of the hospital, the same as any department of its service. It is in charge of its executive officer, but has its special subordinate head, the superintendent of nurses. It is maintained from the annual income or appropriation. Its pupils are lodged, boarded, and paid from the same appropriation as the other officers and employees.

The methods of instruction, routine of work, experience gained, and results obtained, are practically the same under both organizations, *provided* each system works harmoniously. The difficulty lies in the fact that under the dual plan there are two organizations

¹ Read before the Boston Society for Medical Observation, March 5, 1883.

working under one roof with the dangerous possibility of becoming ultimately involved. The nursing force is in a position to derive authority and execute commands given by two different governments, and only with great tact and forbearance can embarrassment, if not collision, be avoided. This dual system may succeed in a hospital where the wisdom and discernment of the managing board can rigidly enforce the supremacy of the hospital authority, always paramount. With these conditions it can fulfill all purposes, and secure the welfare of the patient.

Such a system to be the best, must have discreet managers in both organizations, and, under all and varying conditions, prove itself just as successful as the second with one central organization.

The management of the training school demands certain recognitions pertaining to the nursing force. The nursing is so closely allied to the general interests of the hospital that the lines of work are almost sure to overlap. The managing committee of the school, to thoroughly understand its work, must comprehend the details, and obtain facts for principles deduced and methods of discipline. To insure this they must visit and inspect the wards, and know the particulars of daily work almost as intimately as the superintendent of the hospital.

The danger is in obtaining only a one-sided view of the relations of the nursing to the hospital. There is an absence of oneness of organization and purpose, a liability to too strong theoretical deductions, and too great an opening for questions of policy and mutual relations. When the training school committee is not composed of persons of rarest temperaments and greatest intelligence, questions of function unavoidably arise; the committee must sustain its prerogatives, and the perils of an involved controversy can only be averted by supreme tact.

The application of this principle is not unlike that of the old and modern methods of asylum management. Formerly all asylums had a medical and business head, both officers of the same board, but not responsible to each other. This arrangement when sagaciously administered with judicious gentlemen as officers worked fairly well. With changes on the board of managers or officers the system almost invariably led to wrangling, and has, I believe, been abandoned, after sad experiences, in nearly every asylum. It has been superseded by the appointment of a medical superintendent, responsible for all departments. The trustees of the hospital are the body ultimately responsible, and being so, whatever system best conduces to oneness of purpose, and is most free from distracting agents, seems best suited to the aims and obligations of a public hospital.

The one object of the hospital is the relief or cure of the patient, and this should never be made subordinate to the training of nurses any more than it should be to the clinical instruction of medical students.

While a hospital may have the most judicious managing board, and the most efficient nursing force, the welfare of the sick in its care and its whole prosperity are largely in the hands of its medical and surgical staff. In order that the staff may accomplish the work it undertakes it must have absolute authority, but only absolute so far as concerns the treatment and care of the patient. The surgeon's orders for the treatment, diet, and management of the patient must be strictly obeyed. The whole strength of the hospi-

tal should be directed to aid his efforts, but the *means* by which the ends are attained should be regulated by the management of the hospital.

I bring this principle forward because the want of it in the celebrated controversy at Guy's Hospital has done infinite harm to the modern system of training schools, and aroused grave doubts in the minds of the medical profession and managing boards as to its practicability. It entangled that hospital in a record as discreditable to its staff and governors as it was pernicious to the sick under its care. The question is not so much of rights as of dangers.

To the staff is given the grave responsibility of the treatment and recovery of the patient. To accomplish this the managers place at its disposal buildings constructed and cared for on correct hygienic principles; wards fitted for the required work with suitable furniture, appliances, and accessories; food, medicine, and instruments; a working force to maintain the running of the institution; a house staff to assist, and a corps of nurses. It is the duty of the executive officer so to regulate these forces as to provide the most efficient means of carrying out the orders of the staff. The existing regulations are made after full advice and concerted action with the staff. These means having been provided and placed at the disposal of the staff no interference should be permitted, but they should be used legitimately. The amputating knife is provided by the trustees, of proper and desired kind, in good condition, subject to the surgeon's call, but if wrongfully used, say against a patient's will, or if it is recklessly or carelessly employed, then the misuse should be called in question. So likewise, the nurse is an instrument to be utilized by the surgeon as a factor in the recovery of his patient, to do his work in *his* way. If, however, she fails in her duty to him it is for the administration to correct, discipline, or remove. The vital point of the disciplinary system to which the nurse is subjected is that she carries out intelligently the doctor's orders. This constitutes the nurse's whole obligation to the medical man. Failing in this the superintendent is answerable to the surgeon for her shortcomings. If instructions are improperly executed or neglected complaints may be made to the person in charge of the nursing force. If general principles are wrong, or being right in theory are neglected in practice, complaints may be made to the executive officer. If he and the staff are in sympathy—and without it nothing goes well—matters are easily set right. The difficulty arises from violation of the principle on which every administrative system is based; that in matters of discipline, such as obedience and behavior, the nurse should be responsible to one head only. The enforcement of this is essential to the due attainment of the very object to which the skill of the staff is directed.

It is a matter of congratulation that both leading hospitals in Boston are pretty thoroughly free from any spirit or action that imputes to them a lack of accord in the above principle. The violation of it, however, has made the relation of the training school to the staff a subject of many a hot and bitter controversy elsewhere.

The scheme of training in this country is so well known to the profession that I need not take your time with a detailed narration, but I desire to call attention to certain general principles. One of the most important is the relation and ratio of theoretical

and practical teaching. The course of study endeavors to teach and perfect the pupil in certain things which by general consent are deemed essential. Illustrative of most elementary duties I might mention the making of beds, giving baths, applications of dressings and bandaging, administering of medicines, prevention of bed-sores, etc. Next might be grouped various duties, for example, leeching, use of female catheter, more complicated dressings, and use of hypodermic syringe. Again, the nurse is taught to observe the more common symptoms of disease, and is instructed how to write a systematic and detailed report of the condition of her patient each day. Further on, she is given the nursing of special cases, surgical, medical, fever, or infectious diseases. She is expected to find out from her manuals and be taught by her superiors something about the special nature of these cases, and the requirements for nursing them. She is taught elementary anatomy, physiology, preparation and digestion of food, ventilation, and proper arrangement of a sick-room. She is taught the relations between doctor, nurse, and patient, what habits to cultivate, and what to avoid. What shall be the exact extent to which a nurse shall be theoretically taught and practically trained in the above examples of the course and the rest of the curriculum, what shall be the correct adjustment between class instruction, private study, and individual work with the patient, is not easy to determine. A nurse is not simply to know *how* to do a thing, she should know *why* it is done, and done in a certain way. A groundwork of thorough teaching, with recitation or "quiz," reinforced by bedside instruction or stated lectures from the staff, followed by oral and written examinations, stimulates a nurse to intelligent action.

It is alleged that by the "new system," so called, nurses are *overtaught*. An investigation of this criticism may, perhaps, lessen its force. So varied are the opinions and peculiarities of practitioners that no universal standard has yet been fixed, nor can it be easily done. In my judgment the criticism does not arise because the nurse is instructed in matters beyond her province, or that any attempt is made to distort the calling of nurse into that of a woman doctor. Does it not frequently originate in the self-complacency of some opinionated or stupid woman, who, holding a nurse's diploma, meddles with the physician's prerogatives, or, through vanity, airs her graces? My anxiety is not that they are *overtaught* but *undertaught*. By this I do not mean that they have an insufficiency of symptomatology, anatomy, or what not, but that the essentials as laid down in the more conservative and elementary manuals are not persistently and at all points thoroughly mastered.

After all it is not easy to say where the line shall be drawn. No one can tell when the nurse may be compelled to act on her own responsibility, or what emergency may arise. The nurse of no training, who has not been taught her proper position, fearing to expose her ignorance, will assume opinions and functions she is utterly unqualified to form or fulfill, and "knows too much." It is the nurse of much training who avoids the great danger of a little knowledge, of knowledge a little beyond what is absolutely required for her duties.

There is great diversity of opinion even in matters that are, by good judges, thought necessary for a well-trained nurse. To illustrate: A prominent organizer

and active spirit in a training school of good repute expressed surprise to me that at the City Hospital the medical formulary of house mixtures was allowed to be in the ward medicine closet. She spoke of it much as the teacher of a young ladies' school would about a naughty French novel in relation to her pupils. She was surprised that the properties of drugs, such as opium, aconite, or symptoms of overdose, were taught to nurses. It is sometimes argued that when the nurse has given the exact dose her duty is done. If ever the day comes when remedies always act as desired, when human fallibility is infallible, such instructions may be out of place. There are few physicians who have not at some time been grateful to a well-trained, intelligent nurse for her prompt, discretionary action. It might as well be argued that properties and doses of drugs should not be taught in schools of pharmacy, because after graduation unscrupulous corner-store druggists prescribe for their customers. It is the use and abuse of gratuitous dosing by pretentious and self-conceited nurses that bring all into question, both good and bad. The nurse who knows physiological properties is none the less valuable; the same system that teaches this also teaches and enjoins upon her to refrain from dosing, but it does fit her to recognize facts that her physician may be glad to know, and cause him to feel grateful for her knowledge.

The use of the hypodermic syringe by the nurse is another instance of the diversity of opinion as to her province. As in the previous cases it is the abuse and not the use that raises the question.

Those having the responsibility of training nurses must utilize the means at command in such a manner as combined experience and meritorious advice demonstrate to be capable of producing the best nurse. The best nurse is not the one who has the most theory, or can make a brilliant show of information of a semi-medical nature, nor is she the best who does her work like an automaton. She is the best who intelligently does those things that contribute most to the patient's relief or recovery, being always loyal to the orders and methods of the attending doctor.

The difficulties always attending a new movement have greatly impaired the results of training schools during their first decade. The material has had much to do with this. At first such pupils were accepted as could be obtained, it being recognized that they were not the most desirable. Many seek training not from love of the work, but purely because a diploma is supposed to guarantee good wages. Another class undertakes the work from a hysterical sentimentality, with no aptness for learning or doing. They have a "mission." Another class regards the service as a condescension. Such women are willing to do anything except the painful, wearisome details, the domestic work which forms no inconsiderable part of a nurse's calling.

Like all new projects improvement comes with a better knowledge of the work. A combination of causes now brings a much better class of women to it. If the time comes when all received are model probationers it may be easier for those having the work in hand to produce the ideal nurse.

Undoubtedly every practitioner has been annoyed, perhaps exasperated, by the disobedience, lack of tact, or other shortcoming of his trained nurse. Unhappily these instances are too true, and it would be a charitable view of the question to accept the situation, not as

the result of any system, but rather as the weak side of human nature, and endeavor to wipe out that which is bad, and show a way to produce the good.

Two years of public or private hospital life cannot remodel a nurse's disposition. Those not familiar with the obstacles cannot appreciate the difficulties encountered in this endeavor. It often happens that a nurse in training, who not only gives excellent satisfaction, but is known to act intelligently, and makes herself very valuable in the hospital, fails of success in private nursing. It is said she does not "get on well" with the family and the cook; is too much given to method, and too little to receiving suggestions; wants too many things to work with, requires too much waiting on, and sundry other criticisms of a like character. I have followed several such cases, and I find that in most of them the complaint is made of recent graduates. Hospital work is unattended by these difficulties; the system itself is such as either make them impossible or smooth the way, and the nurse is restrained from error by the discipline of the institution. In family nursing she meets with new surroundings, a change in everything except a patient to nurse. This same nurse, in time, finds out how to avoid complications, adapt herself to varying conditions, learns policy, and gives excellent satisfaction.

The public, as represented by the families of the patient, are frequently more at fault than the nurse. Most persons deem themselves competent to pronounce verdict on her work and her methods, and she failing to meet their views is adjudged as coming short in her offices. Although the public have a right to judge a nurse, she is often more sinned against than sinning.

On the contrary many hospital nurses who compass their training, receive the requisite experience, and obtain only passable records, subsequently in private nursing give invariable satisfaction to doctor, patient, and the family, and acquire a good name, impossible in the hospital, because brought in strong comparison with those who, as a rule, are superior.

Time will bring a better understanding, with progress in methods, with greater distribution of nurses, each year increasing their experience, and a better appreciation on the part of the public, and, may I add, the medical profession.

Hospitals have been the first to reap the benefits, and they have been many and salutary. Whatever doubt there may be with the public, however unfortunate any physician may have been in an unhappy sequence of different nurses who fail of his commendation, whatever question may arise as to methods or deficiencies in the system, the hospital itself has immeasurably advanced in the care of its patients. The patients receive treatment, care, and kind offices that were impossible formerly, and which may be looked upon as a pledge of better things yet to come. Nothing would more surely prove the efficiency of the present system than the expressions of alarm that would arise if an effort were made to abolish it and return to the old ways.

— Two kilogrammes of No. 3 shot and five or six bullets were administered by an Italian physician (*London Medical Record*, May 15th) in a case of ileus. This, with prolonged insufflation of air by the rectum, effected complete relief of the invagination, and the patient made a good recovery.

SEA-SICKNESS ; ITS TREATMENT BY BROMIDE OF SODIUM.

BY G. L. WALTON, M. D.

THERE seems to be a prevailing impression that bromide of sodium is of value in sea-sickness. The introduction of the bromides for this purpose is not new, but general attention was first called to it when Beard, in 1880, in a popular treatise, took up the subject systematically and showed that it was bromidization which prevented sea-sickness, not the exhibition of moderate doses of the bromides.

So confident was this writer of the value of his discovery, that in the addenda to the fourth edition of the work alluded to appears the following statement: "The great dread of sea-sickness has disappeared at last; only those suffer from it who prefer to do so." The directions given are to commence taking bromide of sodium in doses of thirty grains three times a day, three or four days before sailing, and to increase the dose to sixty or ninety grains three times a day, and to continue at the dose producing marked bromidization (stupor, weakness of the limbs, etc.) until all danger of sea-sickness is over. The theory advanced is the comparatively old and unsatisfactory one, that sea-sickness is due to a series of minute concussions. The effect of these concussions is neutralized by the bromides, the bromide of sodium being preferred partly on account of its large percentage of bromine, and partly on account of its mild action on the stomach, the latter quality being desirable, although the symptoms which are referred to the digestive tract are primarily of cerebral origin.

There is little doubt that sea-sickness is a cerebral trouble (although the concussion theory is hardly tenable, for reasons which will be stated further on), and a medicine which stupefies the cerebral centres will, if used in sufficient doses, prevent it, as will, indeed, the continued inhalation of ether. The question is, however, has the remedy been found which is sufficiently practicable as well as effective to justify its adoption?

The knowledge of the bromide treatment has spread so rapidly that physicians are often consulted as to the advisability of trying it, and it is well to form a definite opinion on the subject. Physicians are already, perhaps, inclined to view this remedy with the opposite of enthusiasm; still, inasmuch as many do so without a definitely grounded opinion, and as others content themselves with telling the patient to try it if he likes, and others fancy that the remedy may be worth the trial, a brief consideration of the subject may not be out of place.

The reasons for discouraging the use of bromide of sodium for sea-sickness are the following: In moderate doses it is valueless, and sometimes causes disagreeable symptoms (depressing headache) which should not be unnecessarily added to the discomforts of the sea-sickness; the efficient dose is too large to be intrusted to the laity, or even prescribed by a physician for a disease of so little danger and short duration.

Bromide in moderate doses (thirty grains or less three times a day) has proved ineffectual so often that the cases in which it seems to have given relief must be looked on with much suspicion. No case has come to the writer's notice in which sufficient ground appeared for crediting its efficacy, while a large number of cases have been reported in which the malady was unaffected by the remedy. This opinion agrees

so completely with that of most physicians who have had opportunity to experiment, that no cases will be cited to illustrate this point, excepting that of the writer himself.

On crossing the Atlantic eastward the weather was comparatively fair, and no sea-sickness was experienced. On the return trip thirty grains of bromide of sodium were taken regularly three times a day, beginning several days before sailing. A depressing headache appeared before going on board, and persisted. As soon as the weather became rough severe sea-sickness came on and lasted, with intermissions, during the voyage. The disgust for the bromide became so great that it was given up after a few days at sea.

On another occasion, as a preparation for crossing the English Channel, fifteen grains each of the bromides of potassium and ammonium were taken three times a day for several days. A similar headache appeared on this occasion, and persisted during the trip, although the water was so smooth that, with the exception of the writer, no passenger complained of the least inconvenience. It was supposed at that time that the headache was due to an idiosyncrasy, but a number of similar cases have since been reported to the writer, including that of a gentleman who, after the use of only twenty-grain doses three times a day, suffered from such severe frontal headache as to be obliged to give up the medicine before sailing, on account of interference with his business.

In regard to the large dose of bromide Beard has said: "For all the members of the human race above the age of twelve or fifteen, it is probably entirely safe to begin with thirty grains of bromide of sodium, and to increase and keep up the action of the remedy until there is a weakness of the limbs, a dullness, a stupor, a tendency to sleep by day and by night, and to fall asleep any time." This plan is neither safe nor easy.

While in Europe the writer was consulted by a gentleman who had taken small doses of bromide on the voyage from America, quite without effect. The question was with regard to the proper dose for the return voyage. The plan of bromidization was explained, though not advised. The gentleman said that he could not at any time judge accurately of his own symptoms, certainly not on shipboard, and still less when under the influence of a drug which was to make him stupid, and inquired what dose might be considered absolutely safe for him. The answer was, thirty grains three times a day. This dose was taken with varying regularity, and naturally without effect.

This case is merely mentioned to illustrate the difficulty, as recognized by an intelligent layman, in judging of one's own symptoms, a difficulty at once enough to prevent placing the remedy in the hands of the laity, even if the treatment proposed were a desirable one. That the large doses may give rise to exceedingly alarming, even if not permanent, effects in a very short time, is illustrated by the following case, which came under the writer's own observation: The case was that of a gentleman who had made some dozen voyages, and had been distressingly sick on all. Having read Beard's treatise, he resolved to give the bromide a thorough trial, and persisted in the use of ninety grains three times a day, because this was the maximum dose mentioned. At the beginning of the voyage he was extremely lively and entertaining, but in a few days he was so weak as to totter about like an old man, and so aphasic as to give up all attempt

at conversation. Much as these symptoms alarmed his wife, he preferred them to sea-sickness, and was only with difficulty induced to reduce the dose. The symptoms lasted through the voyage of fourteen days, and for certainly some weeks after, since which time the writer has heard nothing of him. Whether the immunity from sea-sickness was due in this case to the bromide cannot be with certainty determined, as the water was comparatively smooth, but even if it were, this result would have been no compensation for the anxiety of his friends.

This is of course an extreme case, but the writer has had occasion to assure himself that alarming symptoms have followed the use of much smaller doses, even under medical direction; occurrences which, however rare, are worth considering, since the disease itself is one of so little danger.

Unfortunately there is little to offer in place of the bromide. No other specific seems to have proved satisfactory excepting in fair weather and in the hands of enthusiasts. Nitrite of amyl has had its turn of popularity, but further experiences, as shown by the numerous letters to the *Lancet*, denying its efficacy and calling attention to its dangers, have reduced its use to a minimum. The ice bag has been claimed by Chapman to be a specific, but seems not to attract much notice. The various mechanical precautions, as inspiring and expiring with the motion of the vessel, succumb at the approach of rough weather. Whether the swinging berths will stand the test of experience remains to be seen, but it is to be feared that they will prove little more than palliative.

A little study of the pathology of sea-sickness will show the improbability of medicinal measures short of actual narcosis proving more than palliative at the best, and that one must resign himself to more or less discomfort until the cerebral centres have become accustomed to the new conditions. That sea-sickness is due to a series of concussions is improbable, first, because the symptoms appear not simply when the vessel is being pitched about in a storm, but also when the motion is gentle and regular, provided it is at all extensive. In the latter case there can be no question of concussions, however minute. In the second place, the recovery in the majority of cases after a few days renders the theory of concussions rather improbable, as the conditions for producing the concussions remain the same.

A more plausible supposition seems to be the following: Pressure of the labyrinthine fluid on the nerve terminations in the semicircular canals, when unusual in direction and intensity, produces disagreeable cerebral symptoms, including dizziness, headache, and nausea. The same symptoms may be produced in affections of the auditory apparatus (Menière's disease) not by unusual pressure, but because the abnormal condition of the peripheral nervous apparatus causes an abnormal impression to be transmitted to the brain, even when the pressure of the fluid remains the same; here the symptoms, though not identical with those of sea-sickness, are of the same general nature, and include dizziness (though generally of a peculiar kind), headache, and nausea. The pitching and rolling of the vessel causes the pressure of the labyrinthine fluid to vary in intensity and direction at every point, and the disagreeable symptoms produced will vary with the extent of the motion and the cerebral susceptibility of the individual. The sickness ex-

perienced by certain persons on riding backwards in the cars is only to be explained in this way, as well as that of those extremely susceptible persons who are made sick by riding even forwards for a considerable time. The length of time required to accustom the cerebral centres to the unusual pressures of the fluid varies of course greatly with the individual, and may extend over a whole voyage.

Acceptation of this theory might lead one to try quinia or salicylate of soda, for which such favorable results have been claimed in Menière's disease. As this step is hardly advisable, we are limited to extremely expectant therapeutical measures. The persistent constipation of sea travel may be anticipated by a seidlitz powder or a little Hunyadi water in the morning, unless the bowels are exceptionally free. At the first approach of sickness, or before, if it is anticipated, the patient should lie flat on his back and remain so as long as possible; adding the motion of the body to that of the ship only increases the discomfort, and often brings on nausea which could have been avoided. It is wiser, if at all sick, to take light food in the berth on waking than to try to get to breakfast, and when on deck frequent attempts of this kind, if possible even directly after vomiting, the recumbent position being immediately assumed after eating, are better than one or two attempts at a meal in the saloon. One can reconcile himself the more readily to inactivity when he realizes that in most cases the sickness is only a question of a few days unless the weather grows decidedly rougher. All more active measures are sure to come to grief, and only add to the discomfort of the patient.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

C. M. JONES, M. D., SECRETARY.

MARCH 5, 1883. DR. BUSH presided.

DR. G. H. M. ROWE read the regular paper on

THE TRAINING OF NURSES.¹

DR. WHITTEMORE said Dr. Rowe has covered the ground of the present system of instruction given to nurses in the different schools in this city so completely that there is but little in addition to be said. Dr. Rowe alludes to the two systems. At the City Hospital the school is under the complete control and management of the hospital. At the Massachusetts General Hospital a separate board of trustees direct the instruction and control of the school, but subject to the regulations of the hospital trustees. The school at the Massachusetts General Hospital was started in 1873, certain wards being given up to their care, the nurses living outside of the hospital. In 1876 they were accommodated with room and board in the hospital, and in 1877 the whole of the hospital nursing was placed under their charge, so satisfactory and so far in advance of previous nursing were the services rendered.

At first there was considerable sentiment in the nursing, but it has mostly disappeared, and nearly all now apparently enter upon the work with the idea of becoming educated nurses, and with the intention of

following it as a life work. Some friction at first existed between the two departments, but it has disappeared, and all work together pleasantly and profitably for both. Family nursing has many requirements distinct from hospital nursing, but the best hospital nurse in most instances will make the best family nurse, as she will possess intelligence, tact, and qualifications, which will enable her to adapt herself more readily to the conditions of the families in which she is placed. But very few of the nurses from the Massachusetts General Hospital have studied medicine as far as is known.

Another point is the treatment of nurses by families. Whenever an opportunity offers I tell them that they go to a family in time of sickness and trouble, not to add to the cares and anxieties, but to alleviate them, and to conform to what is most for the comfort and convenience of the family. Believing, however, that they are educated and trained for their work, and I think that they are above the ordinary domestic and servant, they should receive attention and consideration as far as is practicable in accordance with their qualification, and not be placed on the level of the common servant.

DR. W. L. RICHARDSON agreed with Dr. Rowe that there were many advantages in having the training school under the direct management of the hospital governing board. At the Boston Training School at the Massachusetts General Hospital the dual system had worked admirably; but such a condition could exist only where the officers of both the hospital and the school were able to work together in such a way as to avoid the numerous causes of difficulty which such close relationship was almost sure to bring about. No one who had had any experience with the old and the new system of nursing would wish for a moment to give up the present class of trained nurses.

Unquestionably there were nurses who failed to satisfy the requirements of either the profession or the public, but if employers would return to the Registry for Nurses true statements as regards nurses this difficulty could soon be remedied.

DR. J. G. BLAKE fully indorsed the system in operation at the City Hospital, both in method and results. The care of the sick was systematically and faithfully attended to, and the results were gratifying to the medical attendants. The difference, when contrasted with the old system, was very marked, in the amount, character, and quality of service rendered. Of course it was only the natural result of the long and careful training and teaching which the system insists upon, but it was a blessed thought, this training of intelligent woman as nurses, and it has helped to lighten the work and anxiety which every hospital physician carries with him during his term of service. In private practice the relief is even greater, and particularly to the man of large obstetric practice is it a boon indeed to know that he is not to be called out of bed to pass a catheter or see if the baby's umbilicus is all right. It might be said that the establishment of training schools for nurses had made in many cases the practice of medicine a pleasure and not a labor.

DR. FISHER remarked that he had often wished a training school for attendants on the insane was practicable. Their duties in many respects were the same as those of ordinary nurses, to which were added special functions incident to the care of the insane. The chief difficulty lies with male attendants, who, in his

¹ See page 1 of this number of the JOURNAL.

experience, were seldom willing to devote themselves long to the care of the insane. Four or five months was the average duration of terms of service among male attendants in the Boston Lunatic Hospital and other asylums in the State. This would barely suffice for learning the rudiments of their profession.

The difficulty was much less with female attendants, as they were neater, more teachable, and willing to remain for long periods. They invariably do better work for less wages and for longer terms of service. Dr. Fisher inquired of Dr. Rowe if any training schools for male nurses existed in this country.

Dr. ROWE replied to the question of the feasibility of training schools for male nurses that in his judgment it was possible to accomplish such a measure in a large, well-organized, general hospital.

There would be many complications and embarrassments in such a feature that do not arise in the training of female nurses. The greatest obstacle is the want of suitable material. The calling is not one men naturally seek; too many avenues are open for more lucrative employment in trades and all branches of business. They are, as a rule, accidental causes that bring male nurses to hospital work, or some deficiency that unfits them for those branches of business requiring full physical or mental development. Again, men well fitted for the work are unwilling to deliberately give two years' time to training, and yet more unwilling to look forward to it as a life labor.

Many male nurses, "wardmasters," have, however, after spending two or more years at the City Hospital gone into private nursing and succeeded admirably in the requirements of a male nurse, finding constant employment, and at prices really above what they are worth.

A training school for male nurses in a hospital already having a training school for women would start with many advantages in the project, but it would require a larger number of men in the wards, involving greater expenditure, more room, greater departure from hospital routine, and a duplication of much work, such as recitations, demonstrations, lectures, etc., which already draws heavily on those having the hospital and school in charge. I am not aware of any organized training school for male nurses in civil life, though some of the European countries possess excellent ones in training men for military hospitals and the field. Those trained are enlisted men.

In regard to training schools for attendants in hospitals for insane I consider them practicable, a thing greatly to be desired, and a measure which is sure to come. The introduction into asylums of trained nurses will cause a demand for trained male attendants, and some time I feel sure will be attempted and, if commenced under proper auspices will succeed.

Whatever asylum attempts this work will reap great benefits, but it should only be attempted, and can only succeed, where the management is willing to be liberal in expenditure, during training, and also more willing to establish graded increase of wages to retain men when trained.

Dr. COWLES said he thought the subject had been well discussed in Dr. Rowe's paper, and that little need be added in regard to the advantages of having trained nurses in general hospitals. It having fallen to his lot to have the management of the City Hospital through the transition from the old system with all its defects to the establishment of the new one, it seemed

to him to go without saying that the training school system is not only the better but the easier to manage. Too much emphasis cannot be placed upon the importance of beginning with a proper organization, and one based upon the correct principles for governing such a complicated assemblage of persons as exists in a large hospital. Placing the training school under the control of the superintendent is undoubtedly the best way, as at the City Hospital, but there are few examples of this plan, and when he was engaged in introducing it there he knew of no other such organization. It promotes unity and harmony of management that contribute largely to success. He would not be understood to disparage the great work done by the training-school organizations outside of hospitals, for they were not only the pioneers in the matter, but there were many hospitals, particularly those under non-medical management, which the new system would otherwise be slow to enter. Hospitals with small means of support may receive invaluable aid in this way.

Every general hospital, if not too small to warrant it, should have a medical superintendent, and now that the new system of nursing is so well established as the best it is time to determine the best plan of organization. It has been said that in the earlier plan there are difficulties arising from the necessity of harmonizing two governing boards in the control and management of the nurses. There are, in fact, under that plan three such factors to be harmonized, as the medical staff is an important element in the matter, as all orders concerning the treatment of the sick must emanate from it.

A medical superintendent having a professional understanding of and interest in the work of the staff, and having control of the nursing department, as of all others in the hospital, can best suit the service to the needs of the staff. The superintendent should be held responsible for furnishing suitable nurses as well as other appliances, and the nurse should obey orders of the physician or surgeon unquestioningly. Should any of the staff misuse these aids it is a matter between them and the superintendent or the governors of the hospital. Therefore it is that all discipline of the nurses, even in their ward work, should belong to the superintendent, because their failure is his failure, and because, also, the other conditions of their life and training in the hospital belong to him. This principle is plain and easy to understand, and careful adherence to it makes impossible many troubles that must arise under the two-headed management. Even in so successful a school as the original one at St. Thomas's Hospital he has reason to believe from what he once heard when visiting there, and otherwise, that there is a chronic state of friction in regard to small matters, between the professional and the nursing staff, which a medical superintendent could remove, greatly to the promotion of harmony and relief from the wear and tear that kills the officer of such institutions. Under this principle such troubles as occurred at Guy's Hospital never need to be.

In regard to hospitals for the insane, where the superintendent has medical charge of the sick, the management of the nursing department is simplest and easiest. There is a large field for improvement in nursing in these hospitals, and he believes from his experience at the McLean Asylum that, in regard to men's wards, the greatest benefit is to come from the employment of women as nurses. They should not be young

women, would be better for training as nurses, and should be adequately paid for their services. It is probably the chief defect to-day of the State hospitals that the nursing departments are too small and poorly paid. Female nurses are employed in the infirmary wards for men in some of the British hospitals. In the Mount Hope Retreat at Baltimore every male ward is attended by two Sisters of Charity and only one subordinate man, and there are seven or more of such large wards. The Sisters have a certain advantage, of course, over the ordinary nurse, but the State of Massachusetts would find it profitable in the long run to employ a well-paid, reliable woman in many of the male wards of its hospitals. The extension of the training-school system, or some modification of it, to hospitals for the insane promises great benefit to them.

Dr. CHANNING agreed with the other speakers that the Registry for Nurses was doing a very excellent work. He thought, however, that the prices the nurses charged were too high. Many families of moderate means needed at times the most skilled nursing, but they could hardly afford to pay \$12.00 to \$15.00 per week for many weeks in succession. Very often a trained nurse, in the sense the word is ordinarily used, was not necessary, but simply a woman of good sense and kindly disposition, who had had a moderate experience with sick people. Such a woman could render efficient aid to a family tired out with the care of sick members.

English nurses he had employed had given him the greatest satisfaction, being quiet and unassuming, and very willing to do anything and everything.

Dr. M. H. RICHARDSON reported

AN UNFAVORABLE CASE OF EMPYEMA.

William M., thirty, blacksmith, born in Ireland, entered the Carney Hospital June 14, 1881. Eight months before was admitted to City Hospital with pleurisy on right side. Remained there seven weeks, and was then discharged. Six weeks later was readmitted to the City Hospital, feeling worse than at first. He was aspirated twice, and again discharged with symptoms alleviated.

Present condition: Complaints of dyspnoea, dry, hard cough without expectoration. Loss of appetite, flesh, and strength.

Two weeks after entrance aspirated by Dr. Garland, and thirty-two ounces of pus withdrawn.

July 5th, three weeks after admission, was referred to visiting surgeon, Dr. Richardson. Operation without ether. Patient was seated astride a chair, leaning over its back. The skin over line of incision was first frozen with ether spray. Free incision under carbolic-acid spray made through oedematous tissues of last aspiration in the ninth intercostal space, right side. Four quarts of inodorous pus evacuated. Chest washed out with one to one hundred solution of carbolic acid, and full Lister dressing applied. During the next two weeks dressings were changed daily and chest washed out. Normal resonance present as far as fourth rib in front and back. Normal vesicular murmur as far down as lower angle of scapula behind. Below that point friction sounds. Discharge continued to August 1st, about the same in quantity and somewhat offensive. Lister dressings now omitted and oakum substituted. Average evening temperature during July under Lister, 99.6° F. Average evening temperature during August and after substitution of oakum, 101.6° F. Discharge

of pus continued in varying amounts till April 10, 1882, when he was discharged, improved. During this time he had gained in weight and general appearance. There had been no cough or other pulmonary symptoms. About two months later he came to the Massachusetts General Hospital in a very filthy condition from neglect in dressings. The discharge had almost entirely ceased. He was very much improved in health, and was about to resume his trade. He was dressed with iodoformized cotton batting several times with complete disappearance of all offensive signs.

He died some time in December, but the particulars of his death are unknown. He was very much emaciated. Nothing was noticed in post-mortem examination of the organs. The cavity of the chest was washed out and a plaster cast made by Dr. Mixer. Windows were made in the anterior thoracic wall to show the shape of the cavity, size, etc. It was found that the upper part of the right lung as far down as the fourth rib was normal in appearance, not adherent, and fully expandible by bellows fastened into trachea. There was a strong adhesion to the fourth rib front and back, which effectually shut off the upper from the lower part of the pleural cavity. In the lung above the fourth rib there were numerous hard nodules, which gave rise to the supposition that phthisis was the cause of death.

The cavity itself had a capacity of about a pint, and its shape was well shown by the cast. It extended upwards and backwards, its upper border in contact with lower edge of fourth rib, and its lower having the diaphragm for its base. The incision through the ninth intercostal space gave very fair drainage, though it might have been made in this particular case one space lower without danger of clogging the tube.

The thorax showed also how greatly the right half of the chest had become contracted. The left side seemed thereby much more capacious. The spinal cord had been exposed, showing marked lateral deviation in the thoracic portion as a result of the contraction of the thorax. Dr. Richardson had made a dissection on the healthy side to show the surgical anatomy of the intercostal spaces. The upper branch of the intercostal arteries were shown running in the groove on the under surface of the rib, accompanied by the intercostal nerve, which had been traced back to the spinal cord. It was shown that the inferior branch of this artery is very small, and of no consequence in the operation of tapping or freely opening the pleural sac. The importance of avoiding the upper part of the space was illustrated, and attention called to the very great downward slope of the ribs.

Dr. Richardson quoted Dr. A. T. Cabot, who advises that in this operation the incision be made from before backwards towards the spine, because one's inclination is always to cut too horizontally. If the cut is made from behind forwards, and the middle of the space is lost, your knife comes up against the under border of the rib, and the large intercostal artery and nerve are injured. By cutting in the other direction error in judging the slant of the rib is followed by striking the upper border of the lower rib, and no harm is done. By this procedure, however, it must not be understood that a transverse or diagonal incision is recommended.

Dr. Richardson showed also a thorax in which there had been an empyema of long standing. The thoracic cavity was seen from below. The right lung was nor-

mal, and capable of full distention. The left was compressed upon the dorsal vertebrae to a mass no larger than the hand, totally incapable of expansion. It was firmly attached to the ribs by two strong ribbon-like adhesions, which ran across the pleural cavity at different angles. The patient was about seventy-five years old, and had probably carried the effusion for a long time.

DR. BOWDITCH spoke of the very interesting specimens presented by Dr. Richardson. There were, however, two points in regard to the first one upon which he wished for further information than he could get from the report or from examination of the specimen.

(1.) What proof exists that tubercular phthisis was the cause of death? The *rational symptoms* might have taken place in simple chronic pleurisy. Neither râles heard under the clavicle before death nor the mere feeling of nodules in the long compressed lungs as observed in the specimen were sufficient to decide the question of phthisis. An incision into the few nodules felt in the compressed lung, and a microscopic examination, or the discovery of tuberculous or caseous matter elsewhere, were needed for more exact diagnosis.

(2.) As the patient had much improved at one time after the permanent opening was made, the question arises whether his subsequent ill-health and death were not owing to his own carelessness in reference to the fistulous cavity. If the patient had been placed under a strong tonic general treatment, and a portion of several ribs had been removed, according to the plan now followed in Germany, it is possible a cure might have been effected. Dr. Bowditch suggested these questions not with the intention of criticising the treatment pursued, but solely because as the facts are presented he could not believe it well for him to fail to present to the Society his doubts.

Dr. Bowditch spoke also of the use of ether, and regarded its administration as always fraught with danger in any case where one lung is compressed by pleuritic effusion. He attended one case in which there was a removal of a part (a little more than an inch) of two ribs. Twice the patient came near dying. Regular breathing ceased, and only after the strongest measures of artificial respiration were resorted to was the patient saved.

DR. J. G. BLAKE said that the specimen was very interesting and instructive, because it illustrated several points in the treatment of empyema which were not always sufficiently considered by physicians assuming charge of cases: (1) the best point for the incision; (2) the size of the cavity to be obliterated; (3) the duration of treatment. In relation to the first point he pointed out that unless the permanent opening was at the most dependent point it was impossible to properly drain the cavity, and the result was stagnant pus and septicæmia, with death following as a matter of course. He has seen two fatal cases recently, the result of operations between the fifth and sixth intercostal space in the axillary line. Pus will not run up-hill any more than water, and unless we find the lowest point and treat the pleural cavity as we would any other abscess of large dimensions, keeping it constantly drained and disinfected, we shall have the case prolonged indefinitely, and our patient in more or less danger of unpleasant and dangerous symptoms. If an incision is made high up a counter-opening should be made at the lowest ascertainable point, so as to avoid purulent collections.

Dr. Clifford Allbutt followed this rule in his early cases, and generally with pretty satisfactory results. When we consider the size of the cavity and the fact that a long compressed lung will be very slow in expanding, and also that the process of granulation inside the pleura is not rapid, we have sufficient explanation why some of these cases are so slow to get well. This consideration should also be remembered as an argument for early operation. He can see very little use, after a fair trial of repeated aspirations, in postponing permanent opening.

In cases where the lung is collapsed and carnified, and no expansion possible, he would be inclined to favor excision of portions of one or more ribs, so as to insure perfect drainage and more rapid and complete contraction of the affected side. This operation, although frequently done in Germany, had not to his knowledge been done in any cases in this vicinity.

DR. TARBELL coincided with the views of Dr. Blake that a low opening was to be preferred. The pus in all ordinary positions of the body sinks to the base of the chest, and the purpose of the opening to secure thorough drainage cannot be in any other way secured. He inquired whether any one knew of cases of empyema treated by resection of the ribs. None had come to his knowledge.

In reply to Drs. Blake and Tarbell, DR. RICHARDSON stated that in future operations he should select the eighth intercostal space or higher, because when the extreme lowest point of the thorax is sought, — the wedge-shaped inferior portion, so to speak, — it had been his experience in some cases to have great difficulty in keeping the passage clear. This is evident when it is considered that the cavity is closed in part by arching upwards of the diaphragm and consequent obliteration of the lower part of the sac through which the tube has to pass. As the cavity contracts it has in Dr. Richardson's experience been necessary to lengthen the tube until it had reached four or five inches. In favorable cases, where the cavity is filled by expanded lung, he thought it made very little difference whether the opening be in the eighth, ninth, or tenth spaces, or higher, but in unfavorable cases a tube passed through the ninth or tenth space causes very great annoyance and discomfort as the disease progresses and the cavity becomes gradually closed.

DR. BOWDITCH, answering Dr. Tarbell's question, said he had seen one case in which the ribs were resected at his recommendation. The existing opening was high, and a piece of rib was removed low down the back, thus giving a double opening. The patient improved very much after the operation. This was the only case of which he had personal knowledge, but many similar cases are reported from Europe, and he considered the operation a useful one.

In reply to Dr. Draper's question if a counter-opening could not be made, by which all difficulties would be avoided, Dr. Blake said this method would generally be advisable and successful, and Dr. Richardson thought the results were satisfactory with a single opening and the use of a double-current catheter for washing out the chest.

Adjourned.

SUFFOLK DISTRICT MEDICAL SOCIETY.¹SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND
HYGIENE.

ALBERT S. BLODGETT, M. D., SECRETARY.

A discussion upon the subject of

DIPHTHERIA

was introduced by DR. C. P. PUTNAM in the following manner:—

"Diphtheria is an acute, contagious, and infectious constitutional disease, in the course of which effusions of fibrine, and cellular changes generally occur either in or on the mucous membranes and the surfaces of wounds. These fibrinous exudations may be called 'false membranes occurring in diphtheria' or 'diphtheritic membranes,' according as they are regarded as essential parts of the disease or accidental accompaniments of it. But no distinction can be drawn between exudation *on the surface* as croupous, and *in the tissue* as diphtheritic, as if they differed in character, and only as a matter of convenience may they be called arbitrarily croupous or diphtheritic according to their position on or in the mucous membrane. When the superficial exudation is detached the mucous membrane is left whole or only denuded of epithelium, but the removal or sloughing of a deep-seated exudation implies removal or ulceration of a part of the mucous membrane.

It has been a mooted point whether, as the question is usually put, 'croup and diphtheria (in the larynx) are the same thing.' Their non-identity has been claimed mainly for the following reasons: Croup or simple membranous laryngitis occurs most frequently in the winter months, diphtheria is fairly distributed through the year. Croup is regarded as a sthenic, diphtheria as an asthenic disease. Contagion is common with diphtheria, and is claimed not to occur with croup. On the other hand it is held that no difference can be discovered between the membrane of a typical case of croup and one of laryngitis of diphtheritic origin; that diphtheria is only more likely to attack the larynx in winter than in summer; that there is less contagion in diphtheritic laryngitis because the stenosis leads to death earlier, and that many cases of light diphtheria show no more asthenic character than cases of so-called croup.

"I do not think the usual way of stating the question presents the best method of solving it, if, indeed, it can be solved at all.

"Idiopathic croup was a common diagnosis not many years ago; now this diagnosis is seldom made. On the other hand we hear of one case after another, that it had been believed to be croup, but was found in course of its development or at the autopsy to be diphtheria. So common is this view getting to be that we may regard it as practically acknowledged that every case of membranous laryngitis is likely to be not idiopathic croup but diphtheritic laryngitis. Many physicians, however, who recognize this general change of view, and believe most cases to be diphtheritic, still maintain that this and that case do not come under the rule, but are true idiopathic croup, and they say with justice that though a thousand cases of croup have been proved to be diphtheritic this fact alone would not prove that the thousand and first must have the same origin. It is fairer to state the question

in this way: Is all false membrane diphtheritic? for then all croup must be diphtheritic; or, Is some membrane non-diphtheritic and simply traumatic? for then though most croup may be diphtheritic some croup may be non-diphtheritic.

"Now false membranes closely resembling diphtheritic exudations are said to have been caused by breathing steam, smoke, ammonia, by the application of corrosive sublimate, arsenic, sulphuric acid, etc. Granting that croup is generally caused by diphtheria, is it possible also that it can be caused by any of the unseen sources of nasal catarrh and bronchitis? At least this has never been disproved.

"*Treatment.* Diphtheria is, in a large proportion of cases, a mild disease, yet at the outset of any attack we know it may, and cannot help fearing that it will, turn out to be one of the most fearful ever met. So we give our medicines and gargles, and when the case comes out well, attribute the success to them. The result is that there is an enormous list of remedies, each one of which is held by its special champion to be nearly a sure cure. Some of these have had their day, and have fallen quite into disuse; others retain a place in the treatment of the disease without being the panaceas they were said to be at first.

"Lactic acid has been much praised for its solvent effect on false membranes, and a writer relying on this has proposed to cure croup by a spray of the acid. But in cases easy to handle I have applied the pure acid and various dilutions of it with great deliberation directly to the membrane without being able to affect it at all unless it be that a superficial part was dissolved, producing an imperceptible change.

"Lime water undoubtedly dissolves false membranes in a test tube, but it has no appreciable effect on membranes in the throat whether in the form of spray or as a gargle.

"The advantage of steam from slaking lime over ordinary steam appears to be purely imaginary.

"Sulphur, as a remedy for diphtheria has passed through many medical journals, which have been freely quoted in the newspapers. Though I have never prescribed it I have several times found my patients using it thoroughly and in spite of much discomfort, but without the least effect.

"Styptic solutions of iron seem to be used very commonly as a local application with the idea of destroying the vitality of the false membrane, and cauterizing the mucous membrane so as to prevent the disease from spreading. I have applied them with great care, but on the following day the patches had enlarged in the ordinary way.

"Pilocarpine is said to effect a removal of the exudation by producing a copious flow of saliva and washing it away, but it certainly has no effect on membranes of any considerable size and thickness unless it may hasten somewhat the natural maceration which leads them at length to be thrown off.

"Compound tincture of benzoin is supposed to prevent the spread of the exudation by mechanically protecting the neighboring mucous membrane, but I have seen the exudation advance over the coated mucous membrane, and apparently nothing has been gained by it.

"Nothing that can be done for a patient with diphtheria is so grateful as applying an ice-bag to the neck. A patient who has found it difficult to drink will often do so with ease after the ice has been on for a while.

¹ Concluded from page 562, vol. cviii.

Swollen glands are often reduced in size, and lose their excessive tenderness, and apparently the swelling is often warded off.

"Agreeable as ice-bags are while the patient is feverish they often become disagreeable when the fever abates, and their influence is decidedly bad when the patient is in a state of depression. On the other hand poultices, the hotter the better, give decided relief to pain arising from swollen glands, and are preferable to the ice when there is little or no fever, or any tendency to depression."

Dr. Putnam also said that he used, as a rule, tr. ferri chl., chlorate of potash, and glycerine, together with local disinfectants, especially when there was membrane in the nasal cavity. He also often gave sulpho-carbolate of soda in as large doses as could be borne without its causing diarrhoea, and apparently with good effect, though it was hard to believe that a real disinfection of the blood could be accomplished by it.

In addition to the matter contained in his paper Dr. Putnam added that he has employed carbolic acid and permanganate of potassium, applied directly to the parts by means of a brush, but has been unable to discern any effect other than keeping the parts clean. The carbolized nasal douche is an excellent means of reaching the nasal mucous membrane when this is the seat of diphtheritic exudation, and can be treated locally in no other way. A part of the carbolized water is swallowed, a part is expelled from the mouth, and a portion flows out through the opposite nostril. The douche has the disadvantage that it is sometimes the cause of acute inflammation of the middle ear from the passage of fluid through the Eustachian tube.

The compound tincture of benzoin has been also applied to the patches and the surrounding mucous membrane, but the exudation remains entirely unaffected by the treatment, and extends over the surface protected by the application as it would do if nothing at all had been done.

Salicylic acid has been vaunted as a positive cure for diphtheria, and is no doubt extensively prescribed in its treatment, but its employment is entirely without effect upon the course, duration, or results of the disease. Sulpho-carbolate of sodium, a quackish-sounding drug, which has been recommended by so good a man as Sansom, has seemed to be of some use. At least, cases in which it has been employed have recovered while others in which it was not prescribed have died. Dr. Putnam now uses it in diphtheria, though it is not easy to say how so small a quantity can produce any very marked result.

DR. J. COLLINS WARREN called attention to the impossibility of a differential diagnosis between croup and diphtheria. The duality of the two diseases has been and is still maintained by many observers, but there is really no distinction between them clinically or pathologically. Dr. Warren has never seen a typical case of croup as described in text-books. False membrane is often expelled from the larynx and air-passages, but this does not constitute croup. Often the more severe cases are those in which there is the least false membrane, and in certain cases no membrane is ever seen.

In severe cases the question of surgical interference in opening the trachea is always liable to arise. There is often great difficulty in deciding whether the operation must be instantly performed or if a longer delay may be justifiable. In a former discussion upon this point Dr. Warren expressed himself as inclined to de-

lay the operation unless there is actual stenosis, when it becomes imperative that the operation be immediately done. In intermittent spasmodic stenosis, even with some degree of dyspnoea, the operation may be still delayed, but if any doubt arise as to the safety of further waiting it is better to open the trachea at once.

Tracheotomy has been often discussed here, but one point is of especial and increasing interest. *The operation is becoming less and less impeded by hæmorrhage.* In one recent case only a few drops of blood were lost. If the incision be carefully located in the median line, and the dissection be carried on slowly, the operation may be absolutely bloodless.

The blood-vessels, even if engorged, lie on either side of the median line, and the operation may be performed with sufficient deliberation to avoid them. It is better to *scrape* or to tear through the fascia and other tissues, rather than to cut them. Attention should be given to the degree of dyspnoea actually present in the case. The hissing respiration alone is not a sufficient indication. The entire thorax should be bared and the chest wall examined. If any considerable degree of actual dyspnoea be present the respiratory movements will be labored, and there will be a depression on each side above the clavicle. A depression at the epigastrium is a much more valuable indication of a dangerous obstruction to respiration, and should lead the surgeon to operate at once.

The prognosis in tracheotomy depends to a certain extent upon the degree of rapidity with which the dyspnoea has been developed. A rapid and increasing dyspnoea is a fatal sign, and tracheotomy usually affords but slight relief. A case recently entered the Massachusetts General Hospital in which a sudden development of dyspnoea was relieved by operation, and was followed by a slow recovery.

The mortality in young children after this operation is very great. The youngest child upon whom Dr. Warren has performed tracheotomy successfully was less than two years of age. In this case erysipelas appeared soon after the operation, but strangely enough the child made a satisfactory though slow recovery. This case is an exceptional one, and does not change the thoroughly established opinion that the prognosis is unfavorable in tracheotomy in patients of less than four years old.

DR. H. S. SOULE, of Winthrop, said that he came to this meeting to obtain a definite idea as to what constitutes diphtheria. In Winthrop the local Board of Health is adverse to the existence of this disease, and visits those sick with it and declares that it is not diphtheria. An acknowledgment that diphtheria existed in the town might interfere with the prospective financial harvest of the landlords, and therefore every effort is made to evade a diagnosis of diphtheria. Collisions between health officers and physicians have been frequent, and a misapprehension of the functions of each is the result. Often the patient with a very sore throat is visited in the evening by the physician and the next morning by the undertaker. Something more than a simple sore throat is present in these cases. Cases are reported as "diphtheritic sore throat" which are undoubtedly diphtheria. The following may serve as illustrations: A patient who is a member of a large family had a sore throat, with exudation, chills, fever, prostration, and all the signs of a serious disease. Succeeding this case five children were attacked with similar symptoms, and presented exuda-

tions in the fauces and roof of the mouth. The eldest has since been paralyzed. The youngest succumbed to croup on the sixth day of the disease. The third patient had a mild attack, and was well in a few days. A sister was then attacked and was paralyzed, and the remaining child was only lightly affected, and made a speedy recovery. The question seems to be, Where shall we draw the line so as not to quarrel with the Board of Health? That there is a great difference between diphtheria and tonsillitis no physician will deny. If there is a patch of exudation it should be considered a case of diphtheria. Even if the patient is entirely well in a week the diagnosis is not affected; it has simply been a mild form of the disease.

The State demands that diphtheria should be reported as well as scarlet fever, typhoid, and small-pox. No doubt cases are often reported as diphtheritic sore throat which are indisputably cases of diphtheria.

DR. PUTNAM remarked that no doubt many cases of diphtheria are seen by physicians which are *not* reported as such. Many cases commence in the form of tonsillitis and never become anything more serious, while frequently cases of tonsillitis suddenly develop into well-marked and virulent diphtheria, and speedily terminate in death. The distinction is an imperfect and entirely arbitrary one. . . .

DR. HAVEN asked if the constitutional symptoms may not often be fully as grave in tonsillitis as in diphtheria?

DR. PUTNAM replied that cases are frequently seen in which the exudation is very thin, and which do not extend to other members of the family, do not present the symptoms of extreme prostration, but yet turn out to be diphtheria. Such cases are very puzzling, as the following clinical record illustrates: A married lady was seized with a moderately severe sore throat, and presented a small thin film upon one tonsil, which, however, had disappeared before the next day. Four weeks afterward her child had diphtheria and died of croup. The mother was then attacked for the second time, and had large thick patches in the throat which were unmistakably diphtheritic. The solution to this confusing history was obtained later, when it was learned that a child-nurse had come to the family four weeks before the child was attacked. Two servants who had slept in the same room with her were seized with severe sore throat, as was also the governess, but they were not seen by the physician. The Board of Health was requested to examine the premises, and in performing this duty the nurse was recognized as a former acquaintance in another house in which diphtheria had occurred. It was found that the nurse had come to this family directly from the infected household, and brought with her a bundle containing wearing apparel, which she proceeded to rip and repair partly in the servants' sleeping-room and partly in the nursery. It is probable that the nurse was in this case the means of conveying diphtheria from an infected family to a healthy one, by which the disease was communicated to five persons, with the loss of one life. The first case was not reported as diphtheria, but in the light of the subsequent investigations it certainly now seems to have been so.

DR. LYMAN considered Dr. Putnam's paper a valuable contribution. The question of diagnosis is a puzzle to all. In many cases there is absolutely no way of deciding. He has often seen cases in which a thin, delicate membrane extended over large portions of

the throat, in which the constitutional symptoms were not very severe. Sometimes in cases in which the exudation is very limited the general symptoms are more alarming than in those which present a large surface of diphtheritic exudation. Dr. Lyman remarked that he had little confidence in any form of treatment except that by carbolic steam, stimulants, ice-bags, and nourishment. Remedies are almost powerless as specifics. Painting the throat with the tincture of chloride of iron is often beneficial, as is also the internal use of the same substance. Often it is impossible to arrive at a satisfactory diagnosis, especially when the cases are not severe enough to be called diphtheria. Cases of sore throat accompanied by headache, chills, fever, etc., but in which no membrane is visible, are more frequently *not* diphtheritic, while in true diphtheria the false membrane is always visible.

DR. PUTNAM observed that the membrane is often present in the throat during the earliest stages of the disease, but in certain cases the exudation appears only at a later period. Occasionally diphtheria commences as a follicular tonsillitis, and not infrequently as a red tonsillitis, and it is manifestly impossible to predict what the condition may be a few hours hence. In these apparently innocent cases the membrane often extends from the tonsil to other parts of the throat, and frequently results fatally.

DR. FITZ said that the examination of the false membrane often reveals only mucus and epithelium. The study of the exudation affords no valuable results except in relation to the subjacent tissues. Much more light may be thrown upon the case by examination of the urine. If albuminuria be present the case must be regarded as a grave one. Every case should be looked upon with suspicion for at least twenty-four hours. Even when the patches of exudation are extending there may be no albumen in the urine. Cases in which no patches of exudation are visible, but in which the mucous membrane is swollen, may be accompanied by albuminuria, and subsequently present the paralysis so often observed after diphtheria. Dr. Fitz said that he differed from Dr. Putnam in regard to the identity of croup and diphtheria. There are many histological and anatomical differences between the membrane which is found in croup and that in diphtheria. The relation of the membrane to surrounding and underlying structures is also strikingly different in the two diseases. Certain cases of obstructive laryngitis are observed in which there is no false membrane, while in some cases there are double membranes in the bronchial tubes and trachea, but none in the pharynx or larynx. The best treatment consists in the application of glycerine and thymol. The mucous membrane sloughs off, leaving an open ulcer, which usually heals very slowly.

DR. LYMAN referred to the necessity in the diagnosis of a recognition of the exact pathological relation of the exudation to the subjacent mucous membrane.

DR. FITZ replied that in diphtheria the exudation is *in the substance* of the mucous membrane, which becomes necrosed and sloughs, and is entirely distinct from the exudation of croup, which is deposited *upon* the mucous membrane, but has no organic connection with it.

DR. PUTNAM stated that the distinction between croup and diphtheria based on the position of the membrane mentioned by Dr. Fitz does not hold clinically. Cases in which the exudation in the throat is

so superficial that it quickly melts off and leaves a healthy mucous membrane are sometimes followed by paralysis. The membrane is not distinctive of either disease anatomically or histologically. The thinnest exudations are often followed by paralysis. There is absolutely no difference in the membranes except in position and degree, and only as a matter of convenience may the superficial be called croupous and the deep diphtheritic.

DR. FITZ remarked that fibrinous exudations are not all alike. A fibrinous pleuritic exudation is not indicative of diphtheria.

DR. KNIGHT asked how far it is necessary to regard the local manifestations in the throat as foci of infection for the patient himself, and how long may infection remain active in clothes, dwellings, etc.

DR. FITZ replied that local points in the throat are considered sources of infection to the individual. A thorough fumigation and ventilation for a few days are generally thought to be sufficient to render dwellings, furniture, etc., safe, as far as infection is concerned.

DR. HARLOW asked how the exudation of diphtheria may be recognized.

DR. PUTNAM replied that if the membrane disappears in a few hours it is probably not diphtheria, while if it remains for some days it is certainly diphtheria.

DR. DEBLOIS exhibited a series of

INSUFFLATORS

for the treatment of diseases of the throat and posterior nares, which possess the great advantage of being easily manipulated by one hand. The compression of a small rubber bulb projects the medicinal substance in the form of a fine powder forcibly in any desired portion of the nasal or pharyngeal cavity. The instruments are simply and durably made, and can be employed for many other purposes besides those for which they were originally intended.

Adjourned at 10.15 o'clock.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. NANCREDÉ, M. D., RECORDER.

DR. ESKRIDGE reported a case of

EXTREME MITRAL STENOSIS, DEATH RESULTING IN A FEW MONTHS FROM SEQUENTIAL LESIONS WITHOUT GENERAL DROPSY.

Charlie, aged fifteen years, died in St. Mary's Hospital during the latter part of December, 1882. In February of that year, during Dr. Eskridge's term of service, he first came to the hospital, suffering from acute bronchitis. The attack ran its course in a week or two, but the heart, during and after the seizure, was exceedingly irritable, frequently beating from 120 to 150 times per minute. Infrequently he complained of pain over the præcordial region. The heart was repeatedly and carefully examined, but no endocardial murmur or pericardial friction sound was heard. No thrill or friction fremitus was felt. He was kept in the recumbent posture, and counter-irritants were applied to the præcordium. At the end of about two weeks he left the hospital, feeling tolerably well, although the cardiac pulsations were rarely below 100 per minute, and a little exercise, or excitement of any kind, would increase them to 120 or more.

In August, 1882, he reëntered the hospital, and was again suffering from acute bronchitis, with free secretion, attended by numerous subcrepitant and large moist, bronchial râles. After the subsidence of the attack, which took place in about a week, a decidedly rough and rather long presystolic murmur was heard. During the remainder of his life he stayed in the hospital, and was engaged most of the time in waiting upon the sick in the ward. Ascending and descending stairs, and active exercise of any kind, greatly exhausted him, causing the heart to beat tumultuously and him to pant for breath. He rapidly grew worse, and by the latter part of November he was spitting quantities of blood rather frequently. The lungs soon became so engorged that the frequent hæmoptysis did not relieve them. During most of December he remained in bed, propped up by pillows. The last two weeks of his life he was air-hungry, and gasped for breath. His extremities were cool and cyanosed, his face was of a dusky hue, and he expectorated large quantities of blood and frothy mucus. No general dropsy existed. Considerable albumen was found in the urine. Physical signs of pulmonary congestion and œdema, bronchitis, pleurisy with effusion, pleuro-pericarditis, and pericarditis with effusion in the pericardium, were present during the last few weeks of his life.

Sectio Cadaveris. Numerous recent and old pleuritic adhesions were found, especially in the neighborhood of the heart. Pleuræ were slightly adherent to the upper portion of the pericardium by means of recent exudate. Considerable fluid containing only a trace of lymph and no pus was seen in the pleural sacs. The pericardium contained several ounces of nearly clear serum. Several patches of recently exuded lymph was present on the outer surfaces of the ventricles. The weight and size of the heart were greatly increased. The right cavities of the heart were relaxed and filled with dark fluid blood and a chicken-fat clot. The left side of the heart was less relaxed, and contained a smaller quantity of blood. The wall of the right ventricle is nearly twice its usual thickness; its cavity is slightly enlarged. The right auricle is dilated. The valvular curtains at the pulmonary orifice appear competent, and show no inflammatory deposits. Tricuspid valve slightly incompetent; otherwise normal. The left auricle with its appendix is enormously dilated. The left ventricle is concentrically hypertrophied. The aortic valve curtains are somewhat thickened, but they are competent, and do not encroach upon the orifice. The mitral curtains are adherent to each other along their entire right borders and along the external portion of their left free margins, thus leaving a space only four millimetres long by two wide for the blood to pass through. The valve has a leathery feel, but neither it nor the surface of the auricle is rough. The mitral valve does not present the funnel-shaped appearance usually seen in such cases, because, probably, the curtains had adhered to each other irregularly, and left the small opening to one side of the centre of the normal orifice. The lungs were dark, deeply congested, and more or less œdematous. Several ounces of clear serum was found in the peritoneal cavity. Liver, spleen, and kidneys dark and congested.

One point in the clinical history of this case is worthy of special attention: The first symptoms directing attention to cardiac disease were the rapid pulse and exceedingly irritable condition of the heart.

These symptoms existed for several weeks, and probably for a few months, before a murmur was audible. An explanation of these, without the presence of a murmur, will be found by a careful study of the diseased mitral valve before us. Neither the valve nor the surface of the auricle is roughened consequently, for the production of a presystolic murmur under such conditions it is necessary for the blood current to meet with sufficient resistance in its passage from the auricle into the ventricle to enable it to set up decided vibration in the valve itself. Before sufficient mechanical obstruction took place at this orifice, the parts being comparatively smooth, to develop a murmur inflammation and beginning adhesions of the curtains to each other were taking place. The latter conditions, although not sufficient to give rise to a murmur, rendered the heart irritable. If the explanation given is the correct one it points to the significance of some irritable hearts where no murmur is present to announce cardiac valvular disease. The length of the murmur was greater than that of any mitral presystolic murmur that he had heard before. It seemed to be divided into two parts, both occurring between the diastole and systole of the heart. The first part was the softer and had less intensity; the latter was very rough and ended abruptly. They corresponded to what Hayden has described as the post-diastolic and presystolic murmurs. He says they always denote great obstruction at the auriculo-ventricular orifice. The post-diastolic murmur, he thinks, is due to the passive flow of blood from the auricle into the ventricle, the presystolic taking place when the auricle contracts. If subsequent autopsies should almost constantly associate the prolonged or double presystolic murmur with great stenosis at the mitral orifice it will be of value in prognosis, as life cannot long continue when stenosis is as great as seen in the heart exhibited to-night.

DR. F. P. HENRY exhibited a specimen of

INTRA-THORACIC ANEURISM,

markedly sacculated, and involving the arch and descending portion of the aorta as far downward as the lower border of the sixth rib. The following notes were taken by Dr. Howard Kelly, the then resident physician, soon after the patient's admission to the Episcopal Hospital.

December 7, 1882. There is a "distinctly elevated area about two inches in diameter to left of manubrium, occupying the first and second intercostal spaces and projecting the cartilage of the second rib. This is also the seat of greatest dullness and of strong bruit and expansile movement. Murmurs heard at apex, ensiform cartilage, and second right costal cartilage. . . . Aortic sounds weak and muffled. Pulse in right radial and axillary strong. In left radial and axillary weak and distinctly delayed. Brachials at elbow visible, sinuous, and atheromatous. Faint bruit in left axillary; none in right. Strong bruit in left carotid, faint in right. Some relation between subclavian arteries. Faint bruit in abdominal aorta. Left pupil always smaller than right."

Under the use of large doses of potassium iodide there was a decided subsidence of the external tumors; also of the pulsation and bruit. The most troublesome symptom, dyspnoea, was not, however, materially benefited.

Death occurred on May 13th, through rupture into the right bronchus, and was immediate.

The removal of the aneurism was rendered difficult by the adhesions to neighboring tissues, especially to the sternum and ribs in front. The fifth and sixth dorsal vertebræ were deeply eroded, and at the site of these erosions the aneurismal wall was entirely gone, its place being supplied by two masses of fibrine accurately fitting into the erosions, but unconnected organically with the sac. They merely acted as plugs. The heart was in an advanced state of fatty degeneration, and slightly enlarged. The aortic valves were perfectly healthy, but immediately above them were marked atheromatous changes. The opening into the right bronchus was about the size of a three-cent piece.

DR. HENRY also presented specimens from a case of

ACUTE PHOSPHORUS POISONING,

consisting of stomach, liver, kidneys, heart and spleen. The phosphorus was taken with suicidal intent during the night of May 7th, and was obtained by soaking the heads of a box of matches in water. Fifteen minutes after swallowing the solution the patient, a male German aged twenty-two, experienced a burning sensation in the stomach, which in the course of a few hours (about six) steadily increased until the pain became excruciating. Copious and repeated attacks of vomiting then ensued, and followed every attempt to allay thirst, which was excessive. On the 8th there was a very loose discharge from the bowels. The patient was admitted to the hospital on the 10th. His skin was sallow and dark, but not then icteric in hue. There was tenderness over the liver, and the line of liver dullness was slightly increased. Severe pain in the abdomen was complained of, and this pain had continued with occasional intermissions since the 8th. The pulse was full and strong, 84 per minute. The temperature was 100° F. The urine contained considerable albumen, but no casts nor other abnormal ingredient. I extract the following from notes taken by the resident physician, Dr. James S. Carpenter:—

May 11th. No pain. Pulse 100; temperature 98.6° F. Patient refuses food, but craves acid drinks.

May 12th. Vomited once, but phosphorus not tasted by the patient as heretofore. Pulse 108 and weak. Temperature, which was 101° F. on the evening of the 11th, now 98.6 F. Decided icterus. Thirst continues.

May 13th. Jaundice increased. Tongue dry and brown, red at edges. Abdominal wall covered with numerous petechial spots. Pulse 126; temperature 100° F.

May 4th. Intense jaundice. One clay-colored stool. Pulse very weak, 32; temperature 98.5. Extremities cold. Bladder relieved by catheter, forty-eight ounces removed. The urine contained bile pigment in large amount, and had a strong odor of phosphorus. The man died at 10.40 A. M., one week, less fourteen hours, after taking the poison. As the patient was not admitted until the third day after he had swallowed the phosphorus the treatment was directed toward relieving pain and sustaining the strength as far as possible.

At the autopsy, which was made very soon after death, the stomach was found filled with a grumous, bloody fluid, but the gastric mucous membrane was quite pale and free from erosion or any sign of inflammation. The folds of mucous membrane upon its

surface were, however, unusually prominent. The liver weighed three pounds fourteen ounces. The anterior border of right lobe and the parts adjacent to the gall-bladder were yellow mottled. Streaks of this yellow coloration extended along the borders of the fissures on the under surface; in parts these streaks were an inch in width. The bulk of the liver was normal in appearance. The gall-bladder was empty. Heart rigid in systole; its valves healthy; slight pericardial effusions.

Lungs: Some old pleuritic adhesions and emphysematous vesicles at both apices.

Spleen and kidneys apparently healthy.

Blood fluid. A microscopical examination of the liver will be made and reported upon at a future meeting.

(To be continued.)

New Instruments.

A HANDY INTERNAL ANGULAR SPLINT.

THE multiplication of surgical appliances, so much in vogue, seems undesirable unless some real gain be thereby attained; but any method which enables the surgeon with a few ordinary ever handy articles to easily manufacture splints in every way equal to the expensive apparatus now necessary in the treatment of fractures should be welcome to the profession. A country practitioner cannot fail to find such of service, while in out-patient hospital service and work among the poorer classes all such devices are invaluable. The need for a cheap and easily-manufactured internal angular splint has long been recognized, and I therefore hasten to describe one which it will take one provided with sheet tin, shears, and rivets, but a few minutes to make. It is a device of Mr. F. R. Troop, a ward-master in the accident room of the Boston City Hospital, though it has been modified somewhat by suggestions of the house surgeons.

A square sheet of tin, A B C D, is taken, whose side is equal to the length from the bend of the elbow to the wrist, or as far as the internal angular is expected to reach. This is folded into a triangle B C D. The next step is the drawing of the lines E F and F G parallel to the sides of the main triangle, and at a distance of one or two inches from the edge, according to the width of splint desired. The corners, C E H and D G J, are then cut off to allow later of the turning down of the sides, and a quadrilateral space, B K L M, is removed, thereby cutting away the corner which would fit into the bend of the elbow, where pressure is undesirable. If the sheet be now placed in a vice along the lines E P and G R successively, the sides E K H P and G M R J, and the corresponding plates on the other side can be turned down through 90° F. so as to form the moulds for the upper and fore-arm. What remains to be done is the rounding of the corners, the removal of a portion of X Y G, to render the splint less unwieldy, and the securing of the pieces together by one or more rivets at the point indicated or elsewhere. After covering the edges with adhesive plaster, and padding with sheet wadding, the splint is ready for use.

The splint will retain the arm firmly at a right angle, but with effort allows a slight inward and outward motion of the fore-arm, from slight torsion at the corner of the splint. To remedy this, methods will readily suggest themselves to the maker: by incorporating

extra thickness of sheet tin on either side of the buttress, or by cutting the portion at X Y G, so as to ad-

mit of the reënforcement of the corner by turning down, rather than removing, the superfluous portion, as indicated by removal of parts included in the dotted lines.

By varying the length of the sides of the triangle any shape can be made and any arm fitted, while by having the angle B acute or obtuse, the splint can be made at any angle of inclination, and will then doubtless be found as useful in affections and injuries about the knee as well as elbow joint.

The aim in the preparation of this splint has been to provide one applicable to all cases, and it was with a view to providing for fractures just above the condyles that the angle F was removed. In dislocations, injuries to the internal or external condyles, or fractures of the shaft, there is no indication for the removal of this point of pressure. For such cases the corner can be made square, little or nothing removed, and thus the strength of the splint be materially increased. The tin is then cut along the dotted line S F, and the upper portion bent upon itself to a right angle, so as to overlap the lower coapting surface and be riveted to it. Those interesting themselves in making the appliance will find that by a separation of the overlapping parts in the centre the corner may be made to assume a curved shape, more suited to fit closely to the inner side of the elbow. With this there is also no possible chance of the splint's working down on the fore-arm, and so causing displacement, as sometimes happens with most other forms of internal angular splints.

First Annual Report of the Provincial Board of Health of Ontario. 1882.

The provincial government of Ontario, recognizing the need of sanitary supervision, have organized a Board of Health, which has during the past year begun its duties, and issued its First Annual Report. The topics presented are as follows:—

Chapter I., Organization of the Board.

Chapter II., Collection of Sanitary Information.

Chapter III., Dissemination of Sanitary Information.

Chapter IV., Investigations into the Causes of, and Remedies for, Various Outbreaks of Disease.

Chapter V., Action taken in Cases of Various Reported Nuisances and Unsanitary Conditions.

Chapter VI., Collection of Statistics of Prevalent Diseases.

Chapter VII., Relations of the Board to Various Classes.

Chapter VIII., Work to be Done.

Soon after its organization a commission of the Board visited several of the State and City Boards of Health of the United States for the purpose of observing their modes of operation, and the result of their observations is reported in Appendix B.

The propriety of occupying a considerable portion of a public document with an advertisement of a private vaccine farm, whose operations have already been the subject of sanitary criticism, is at least questionable. Had the Ontario Board visited the State Board of Connecticut, or at least perused its Fourth Annual Report, the advertisement would doubtless have been omitted, or at least modified in its expressions of approval.

Allen's Human Anatomy. Section IV. Arteries, Veins, and Lymphatics. Philadelphia: Henry C. Lea's Son & Co. 1883.

Prof. Harrison Allen begins this section of his great work with some general considerations on the blood-vessels. Instructive and judicious as they are, we nevertheless are inclined to criticise some points. We had thought that Suquet's *circulation derivative*, which he accepts, had literally been found wanting, and we regret that he recognizes only one kind of erectile tissue. We believe that the form of cavernous tissue which Henle calls the compressible should be distinguished from the erectile proper. We are glad to meet with Mr. Nunn's plan of arterial distribution on the limbs.

There is no need of much comment on the account of the heart, which is given first in general and then in detail. We are disposed to question the statement that both ventricles consist of a cavity and a conus. There is a long extract from Pettigrew's interesting researches on the arrangement of the muscular fibres of the heart. There is a very satisfactory section on the anomalies of the heart and those of the development of the great arteries.

One point in the treatment of the heart seems to us very wrong, and is, we imagine, the result of one of those careless oversights it is so much easier to point out in the works of others than to avoid ourselves. We read on page 343: "The plane of the aortic orifice looks downward, forward, and toward the left. The plane of the pulmonary orifice looks downward, backward, and toward the left." At this point a foot-note refers to Mr. John Wood's well-known paper in the third volume of the *Journal of Anatomy and Physiology*. Feeling surprised at this, we referred to the paper in question and found that Mr. Wood speaks of the "plane of the aortic opening having an inclination downwards, slightly forwards, and towards the right side, and the pulmonary downwards, backwards, and towards the left," which is a very different story. Apart from any other discrepancy, it seems to us that a plane having length and breadth but no depth must be held to "look" in a direction perpendicular to its surface.

The descriptions of the arteries are accompanied by

many physiological and surgical digressions that we think will be interesting to the practitioner. Particular attention is given to the important point of collateral circulation. The external carotid is divided into a superficial and a deep portion, the latter being within the parotid gland, but the point of entrance (on the inner, not the lower, side of the gland) is not mentioned, and the internal maxillary is said to arise behind the gland, which is incorrect. The difficult subject of the cerebral arteries is very well handled, and there is a very instructive diagram of the relations of the posterior communicating artery, but we are sorry to find no mention of the anomalies of the circle of Willis. The persistence of the omphalo mesenteric artery is given as a possible cause of constriction of the intestines.

The veins usually receive but little attention both from teachers and students, and yet in some respects they are better worth knowing than the arteries. They have been treated according to their importance by Dr. Allen, and we have therefore more than ordinary satisfaction in welcoming this part of his work. He dwells on the interesting fact that the facial vein is not formed by venules but by a series of communications with other veins, and that the blood from the deeper part of the face tends to the orbit. This at once furnishes an explanation of at least one reason of the greater danger of carbuncle of the upper lip than of the lower. The development of the veins also is discussed.

Next in order are the lymphatics, and then the spleen and other ductless glands. We regret that the description of the minute structure of the latter organs is not as complete as might be expected in a work of this kind. To conclude, the part before us presents great merits, but, it seems to us, more defects than its predecessors.

T. D.

Student's Guide to Diseases of the Eye. By EDWARD NETTLESHIP, F. R. C. S., etc., etc. Second American from the second revised and enlarged English edition, with a chapter on Examination for Color Perception, by WILLIAM THOMSON, M. D., etc. Philadelphia: Henry C. Lea's Son & Co. 1883. 416 pages.

It is not very long since we had occasion to notice favorably the first edition of this book. The present edition has been carefully revised by the author, some passages struck out, and others added, the net result being an increase in size, and a general improvement. The chapter on symptoms, which opened the former edition, has been replaced by one on Optical Outlines, and the "functional" disorders of sight have been brought together in a separate chapter. In the American edition there has been interpolated a chapter by Dr. Thomson describing the method of testing railroad employees for vision, color-blindness, and hearing devised by him, and in use on the Pennsylvania railroad. It is an excellent manual.

— Are French flats healthy? Yes, very. Are the people in them healthy? No. Why? They have to starve and go half naked to pay the rent. Why are these flats called French flats? To distinguish them from American flats. What are American flats? The people who live in French flats. — *Life*.

Medical and Surgical Journal.

THURSDAY, JULY 5, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

SOME MEDICAL ASPECTS OF THE TIME OF THE STUARTS.

It is not without both interest and instruction to medical men of the present day to learn of the state of their art as exemplified in the practice of two or three centuries ago. Fortunately the social and political prominence of a few of the men of those days, with something which at the present time would perhaps be called toadyism, has secured to us medical information which otherwise we should never have gained.

Dr. R. L. Macdonnell, in a paper read last fall before the Athenæum Club, has collected some of these facts, which at once illustrate the medical practice of the time, and convey an agreeable savor of professional gossip. The address is published in the *Canada Medical and Surgical Journal* for May and June.

Among the physicians of James I. was Sir Theodore de Mayerne, who played a prominent part in the medical world of his day, being physician, besides, to Henry IV. of France, and both the Charleses of England. The world owes to this man (whether it be matter for gratitude or reproach) the introduction of calomel into medical practice, and into the Pharmacopœia, of the first issue of which, by the way, he was the compiler in 1618. His foreign birth, his knowledge of new subjects, especially of chemistry, in which he was really an expert, and perhaps more than all, his *success*, made him an object of dislike to many of his contemporaries. One of them, for instance, complains that Mayerne gave advice to a certain patient "without consulting the will and pleasure of God Almighty, an arrogance unheard of, and savoring more of the atheist (as too many of 'em are) than a pious physician." He accuses him, too, of prescribing a nostrum, "the great empirical medicine, from which his father, Turquetus (usually by the French nicknamed the Turk), had got great reputation by selling it publicly on the stage, whom Sir Theodore, in his younger days, had attended in that employ." John Chamberlen, writing to Sir Dudley Carleton, August 11, 1612, mentions Mayerne's appointment as having given dissatisfaction. "Much envy was caused by Turquet's (Mayerne's) preferment, who hath £400 pension of the king, £400 of the queen, with a house provided him, and many other commodities which he reckons at £1400 a year."

Sir Theodore, for the benefit of posterity, left, besides many published volumes on subjects connected

with the prevalent dispute about chemical remedies, nineteen manuscript volumes, folio and quarto, of records of cases, exclusive of a volume relating entirely to the health and habits of James I. His *clientèle* comprised many of the distinguished people of the time. The later volumes, entitled *Ephemerides Anglicæ*, relate to the disorders and cures of persons of quality of both sexes. The whole is written in very bad Latin, with a sprinkling of French words. Where the diseases are those of a nature not creditable to the moral antecedents of the sufferer, a *nom de guerre* is used. Thus Buckingham, who was constantly in trouble, is called "Palamedes," and Prince Charles is "Monsieur de la Fleur de Lys." Rochester ("Le Cardinal Joyeux") is continually being treated for "debilitas," although he is described as being "admodum salax." Here is a portrait of the Marchioness of Buckingham:—

"Januarii 24, 1622. Madame la Marquise de Buckingham. Annum ætatis agit xix. Habitus gracilis, corpus *μονογραμμον*. Temperamentum ex sanguineo biliosum. Faciei color floridus. Mores compositi. Summa cum gravitate modestia. Vitium conformationis in spina dorsi. Gravidæ est et credit longissimum partus terminum fore diem Annunciationis B.V.M. 25 Martii."

Again:—

"Preparationes missæ ad Ser Walter Raleigh; parandæ pro Ser Roger Aston."

"My lord Duc de Lenox, Diarrhœa a liberiori victu."

"Madame de Hadingthon, Affectus hystericus et melancholicus."

Mayerne was in charge of Henry, the Prince of Wales, whose sickness, spoken of by some of the physicians as a kind of "bastard tertian," was felt to be a malady before unknown. Other cases like it began to occur, and Mayerne's description of the prodromata, which lasted seven days, the "continual headache, laziness and indisposition increasing," as well as of the subsequent epistaxis, diarrhœa, and delirium, leaves little doubt that the "new disease" (as it was called in the case of the Countess of Oxford, who died of it) was typhoid fever. The prince was bled and purged, the head was shaved, and cupping glasses were applied to the back of the neck. On the following day "a cocke was cloven by the back and applied to the soles of his feet, but in vaine." After the twenty-third day all hope was abandoned, and he died on the twenty-eighth. Mayerne was much criticised by the profession in his own and other countries for the treatment, and after one Butler, of Cambridge, who was called in, had expressed himself that the patient should have been "blooded earlier," and should never have been purged, Mayerne withdrew. Subsequently when the king requested that he should take sole charge of the case, Butler having been dismissed for his rudeness, Mayerne refused the responsibility.

It is especially interesting to note how the friends of the patient meddled in the treatment. Sir Walter Raleigh, who was a friend to the young prince, sent from the Tower his famous fever cordial. The queen

specially recommended it, since she herself had, in a previous illness, derived much benefit from it. With a discretion not unparalleled in modern times Sir Walter sent with the cordial a message: "It would certainly cure Henry of a fever except in case of poison." So great was the public faith in this cordial that the very fact of the prince's dying at all was looked upon as proof positive that he must have been the victim of a murderous conspiracy. Sir Walter Raleigh was, by the way, very fond of amateur therapeutics. In a letter from John Chamberlen to Sir Dudley Carleton, in 1612, there occurs this passage: "The widow Countess of Rutland died about ten days since. Sir Walter Raleigh was slandered to have given her certain pills that despatched her."

James I. seems to have died of gout and chronic Bright's, with an intercurrent attack of ague. The autopsy, from which some whimsical conclusions were drawn, nevertheless is of scientific value so far as it recorded actual appearances, namely, atrophied kidneys, enlarged heart and spleen, even though the significance of these observations was unknown to the physicians. The explanation made by Sir Simon G. Ewes of the cardiac hypertrophy was that "the greatness of the king's heart argued him to be as very considerate, so extraordinary fearfull, which hindered him from attempting any great actions."

According to another account the head was found so full of brains that they could not keep them from falling out, "a great mark of his infinite judgment," but his blood was "tainted with melancholy, and the corruption thereof the supposed cause of death."

During the fatal illness of the monarch the old women of both sexes flocked about him and proffered all sorts of nostrums and advice. The Buckingham family went so far in their officiousness as to bring upon themselves the suspicion of trying to poison the king. They surreptitiously put plasters on his wrists to break up the chills. The doctors resented the interference, and refused to continue the treatment. Promises of good conduct having been made they saw his majesty through his fifth, sixth, and seventh fits. Again dissatisfied with the progress of the case, the Buckinghams applied their plaster, but the patient grew worse, and it is a matter of history that the royal surgeon had to get out of his bed to remove it. Dr. Craig was particularly incensed at these proceedings, and, according to Dr. Fuller,¹ "he uttered some plaine speeches, for which he was commanded out of court." The Duke of Buckingham secretly administered a julep, after which the king was said to have grown rapidly worse, and died, as our author says, for want of a shilling's worth of quinine. We may doubt if with such a heart and such kidneys even the quinine would have much prolonged his days, but the point suggests to one of imaginative tendencies an interesting question as to what would have been the effect in a primary therapeutic as well as in a secondary political point of view of modern medical methods in some of these cases.

Dr. Macdonnell remarks with no little ingenuity,

¹ Church History.

and, perhaps, with some truth, "Had Henry VIII. had a nineteenth century physician the disease from which he suffered would not have descended to his unborn children. Catherine of Aragon might have been the mother of many Tudors, the Stuarts would never have been heard of, the Reformation postponed, and Henry himself would have been talked of to-day as a model father and husband. Queen Mary's cruel disposition, if not the actual result, was certainly intensified by the disappointment which followed her fruitless marriage. Sir Henry Halford thinks that a course of aloes and iron might have changed the course of events in England and Europe."

We may on a future occasion have something further to say on this subject. It is one that certainly shows that professional life in some of its phases was not very different in the seventeenth century from that of to-day.

THE BOSTON LUNATIC ASYLUM. FORTY-FOURTH ANNUAL REPORT OF THE SUPERINTENDENT.

WE have just received the report of this old and valuable institution for the current year, which has proved an important one in the history of the asylum by reason of the inauguration of various changes in its administration under the direction of the superintendent, Dr. Theodore W. Fisher. For a number of years the institution had been allowed to fall behind the times in the matter of accommodations for the treatment of patients, under the feeling that the buildings, which represented those ideas of the management of the insane prevalent forty years ago, were so entirely unfitted for present methods that the expenditure of money to change them was useless until a radical overhauling of the whole institution could be made, and new buildings be substituted for the old. The original buildings partook more of the nature of a prison than of a hospital. "The doors were thick and solid, the windows heavily barred, and in one corner of each room was a triangular plank seat built into the brick walls. In some of these seats were staples, to which a violent lunatic in restraint could be fastened in a sitting posture." The ventilation was exceedingly inadequate. No provision was made for heating any room independently. The corridors were dark by day, and until 1851 were never lighted even at night.

Dr. Fisher assumed charge of the asylum under these unfavorable circumstances, but with an assurance from the trustees that something should be done to adapt the buildings tolerably to their purpose until something more radical could be done. In pursuance of this determination an appropriation was placed at the disposal of the superintendent, and the work has been well begun. A building erected in the old days, containing cells for the violent patients, but which more humane methods have rendered no longer necessary, has been converted into a boiler room, and steam-heating apparatus has been introduced. Ventilation has also been secured by the building of two

air-shafts from the basement in each wing, whereby the foul air is drawn from the rooms, and carried twenty feet above the roof. The dining facilities, which were before very imperfect, have been remedied by the erection of two new wings, containing six dining rooms, which will accommodate thirty persons each, and which command a good view of the harbor. Regarding the need for still greater improvements the superintendent says:—

"The hospital will now accommodate two hundred patients reasonably well. More room, more wards, more sunlight, and larger grounds for work and exercise, are the important things which must always be lacking here. The hospital, like all others in the State, is full, and the pressure for admission continues, and will increase. The friends of those we are unable to accommodate are always urging us to take just one more. They cannot see why they should be discriminated against in the occasional admissions now possible here. And it is unjust that three fourths of the city insane should be boarded in distant State hospitals, while the sick, the criminals, and the paupers are provided for nearer home. The insane, above all other classes, should be within easy reach of friends and home. It conduces to their contentment and happiness to feel that they are still residents of the city to which they belong, and not banished from familiar surroundings as well as from familiar faces. Their residence in hospital is often prolonged for years, and to be near home is the next best thing to being at home. To be banished so far from home as to debar them from the frequent visits of relatives and friends is a hard lot indeed. I find the harm resulting from a free visitation by friends infinitesimal compared with the good. Insanity is a disease which needs peculiar treatment, such as hospitals alone can afford, but it is not necessary, in my opinion, to isolate the patient for long periods from his friends at any stage of the case. A visit of short duration once a week is not hurtful, but beneficial, in my experience. With this belief I cannot but think it wrong to send city patients to State hospitals, entirely beyond civic control and supervision, where their poorer relations are prevented by the expense in time and money from visiting them. Boston, like every large city, should have within her limits hospital accommodation for every insane citizen."

The average weekly cost per inmate was of course increased during the past year by the extraordinary expenses above alluded to, but deducting these, the rate is only \$4.95, while that of the previous year was \$5.69.

The use of the camisole (the only form of restraint practiced) was given up for five months as a matter of experiment, though it was not claimed to have been absolutely abandoned. It was then used in a case of extreme exhaustion with excitement when it seemed necessary to save life, and has been sparingly used since, in similar cases, in pursuance of the policy not to forego it absolutely if a case seems to demand it.

The report contains a tribute of respect to the

memory and work of the former superintendent, the late Dr. C. A. Walker, of whom his successor says:—

"He was a man of strongly marked characteristics, of great energy, of sound judgment, large-hearted, and generous to a fault, making few enemies, but hosts of warm and lifelong friends. His humanity in dealing with the insane, his devotion to the interests of his patients, his persistent efforts for their thorough and permanent restoration, his patience in listening to the most tedious recital of suffering, and his open hand in the bestowal of relief, endeared him to all who knew him, or were benefited by his acts of kindness. His services for the city were held in high esteem by many successive Boards of Visitors and Directors. When, in ship fever and cholera times, he volunteered to go down to the sheds at Deer Island; or, later, he first set the example of the disuse of cells in the treatment of the insane; or, later still, endeavored to secure better hospital accommodation for the city's insane,—he always had the relief of suffering humanity nearest his heart."

MEDICAL NOTES.

—A Pittsburg lady doctor says that women can understand woman, and it often does a patient more good to talk to her of spring bonnets and wraps than is effected by medicine. Husbands and fathers want to look out for that lady physician. Instead of recommending fifty cents worth of aqua pura for a sick headache, she may prescribe a \$14 bonnet and a \$25 Surah overskirt, or something that way. — *Norristown Herald*.

—A druggist in Paris has been condemned to a week's imprisonment and 2000 francs damages for repeated sales of morphine to a lady, amounting in seventeen months to 693 grammes. His customer at first presented the medical prescription, without which no poisonous drug can legally be supplied, and on her second purchase produced the same prescription, but after this she went constantly to the shop without bringing any prescription, and she is now in a lunatic asylum. The husband then took legal proceedings, and has recovered damages.

Correspondence.

LETTER FROM BALTIMORE.

BALTIMORE, June, 1883.

MR. EDITOR,—Since the last letter of your Baltimore correspondent a great deal of interest to the public and the medical profession has taken place in this community. Too much, indeed, to be mentioned in detail in such a letter as this, but a few of the more important facts may be briefly noted. Our medical societies have been unusually active during the last "season," if I may use the term, and particularly the Clinical Society. This Society is composed principally of the younger and middle-aged men with a wise leaven of the older ones, and it is an encouraging sign, in connection with this and our other medical societies, that the younger men are participating more largely and frequently in their transactions than heretofore.

The influence of the Johns Hopkins University is beginning to be felt, and the spirit of original research and true scientific investigation have been fully aroused in the medical profession.

The Eighty-Fifth Annual Meeting of the Medical and Chirurgical Faculty of Maryland began on the 24th of April last, and continued until the 29th. It was one of the most successful meetings ever held by this Society. The reports of sections were unusually full, and quite a large number of original papers, some of special merit, were read. The feature of the occasion was, of course, the annual oration, delivered by Dr. John S. Billings, United States Army. The subject of his address, Medical Bibliography, was treated in his well-known skillful and interesting way. The address is well worthy of careful perusal, and will be published in full in the Transactions of the Faculty.

Dr. John N. Mackenzie, in a paper read before the Society at this meeting, claims to have localized experimentally an area of reflex excitability in the mucous membrane covering the turbinated corpora cavernosa of the nose. Irritation of this area gives rise to cough, and the cough is most constantly produced by artificial stimulation of the membrane clothing the posterior end of the inferior turbinated bone and that of the erectile body on the septum immediately opposite.

Another interesting matter was brought before the meeting by Dr. St. George W. Teackle, State vaccine agent, who was requested, as "an expert," to pronounce upon an eruption which had appeared upon the udders of four Alderney cows, on a farm near Baltimore, about the middle of last January. From the appearance of the eruption, its history, and the surroundings of the cattle, Dr. Teackle pronounced it genuine vaccinia, spontaneous in the first case. With a crust from No. 1 he inoculated five primary and three secondary cases, and reported success in all but one primary and one secondary. In all the cases there was great fever and glandular swelling. Dr. Walsh, of Washington, experimented with a crust from No. 1 with negative results. Dr. Teackle also inoculated a heifer, eight weeks old, with a crust from No. 1, April 20th, and exhibited the calf before the Faculty, April 28th. As, in the discussion which followed, the spontaneity and genuineness of the supposed vaccinia were questioned, a committee was appointed to watch the progress of the eruption, and report at a future meeting of the Faculty. The committee has not yet reported, but your correspondent understands that a majority of the committee do not regard the eruption as genuine vaccinia. An interesting fact in regard to the investigations of the committee is that in three primary cases inoculated from the same crust as was the heifer, and made by a member of the committee, the only result was the raspberry tubercle so commonly met with last winter, at least in Baltimore, as a result of vaccination with bovine virus.

The advent of hot weather has caused all our medical societies to adjourn until the autumn.

Many of the readers of the JOURNAL are no doubt aware that the Johns Hopkins Hospital, our "pride and boast," is at this time almost ready to receive patients and offer clinical advantages to students. Indeed, the trustees of the university and hospital are even now considering the earliest time for opening the hospital and starting the medical school. The buildings of the hospital, which are nearly finished, and with whose completion it is expected that patients will be

received and medical instruction given, are the administration building and annex, two private, four public wards, and an isolating ward, the autopsy room, dispensary (including the amphitheatre), laundry, kitchen, and nurses' home buildings. Three professors for the medical department of the university have been selected. Professor Remsen of chemistry, Professor Martin of biology, and Dr. Billings of hygiene. It is, however, not as yet known whether the last-named gentleman will accept.

A controversy in the boards of trustees of the university and hospital, which has been agitating the community for about a year, and which, unless speedily and finally settled, seems likely to imperil the success of both institutions, has at length reached a climax. Many months ago the minority of both boards, particularly that of the university, finding the majority were bent upon carrying out measures which they conceived to be illegal and contrary to Mr. Hopkins' intentions, — implied if not expressed — appealed to public opinion in speeches and through the daily press. This agitation has been promoted by various contributions from outsiders, some now residents of the State, who think themselves entitled and qualified to speak in the matter.

In an address delivered on the 30th of January last before the Young Men's Christian Association of this city, Mr. John W. Garrett, President of the Baltimore and Ohio Railroad, and a member of both boards of trustees, made a violent attack on the management of both university and hospital. He says: "The grounds and buildings of the hospital have already cost more than \$1,200,000, and more than nine years have elapsed since the death of the founder, and not one patient, nor one of the suffering indigent sick of Baltimore, has yet received any benefit from this vast expenditure." And he further asks, "What has the university done?" although it has, with great expense, been located in the midst of the city instead of at Clifton (the country seat of Mr. Hopkins, just outside the city limits), which was designated as its situation "not only by the well-known will and instructions of the founder, but by the absolute requirements of law." He is glad, however, to inform his hearers "that a committee, appointed by the board of trustees of the hospital, recently demonstrated that, with proper systematic effort, important and desirable portions of the hospital can be opened in the autumn of the present year, and that an earnest minority in the board of trustees of the university is urging that medical classes be at once established."

This address has been published in pamphlet form, and, probably, five thousand copies distributed in Maryland, with the avowed object of inducing the Legislature to alter the charter of the university, and compel the trustees to remove to Clifton the branches now established in Baltimore. A hundred copies of the pamphlet were sent to the university with the singular request that they should be delivered to the students to whom they were addressed.

A semi-official reply, in the form of an open letter, signed by a majority of the trustees, was published shortly after the delivery of Mr. Garrett's address, and was thought by many to be conclusive. Volunteer contributions, however, continued to appear, and Mr. Garrett's address to be referred to approvingly by the daily press, so that a more complete reply seemed called for. Accordingly, on the 23d of last month,

the Hon. George Wm. Brown, chief judge of the city, and himself a member of both boards of trustees, addressed an open letter to Mr. Garrett, in which he refutes the latter gentleman's charges, answers his queries, and completely vindicates the action of the majority of the trustees. The following is a brief summary of his letter, which will be published in pamphlet form:—

Neither the charter nor Mr. Hopkins' will designates Clifton as the seat of the university. The charter, indeed, provides that it be located in Baltimore County, but a codicil to the will authorizes the trustees to ask for and obtain any alteration to the charter which they may think proper. In accordance with this provision the trustees obtained an act of legislature altering the charter, and authorizing them to "establish branches of the said university in the city of Baltimore, and to hold, or purchase and hold, all property in said city needed for the successful conducting of the branches of the said university in the said city, and to keep and maintain a principal office in the said city for the conduct of the business of the university."

Under this act they erected the necessary buildings, and established the branches of the university at present in existence. The university thereby acquired vested rights which the State Legislature is powerless to violate by enacting that the branches already established must be transferred to Clifton. Judge Brown reminds Mr. Garrett that the principle governing such action was settled by a case involving the possession of its Pittsburgh and Connellsville branch by the Baltimore and Ohio Railroad. He also reminds Mr. Garrett that shortly after Mr. Hopkins' death the trustees began to improve the Clifton estate with a view to locating the university there at once, but after the expenditure of a considerable amount of time and money it was decided to open the university in the city, Mr. Garrett being one of those approving this course of action. Clearly if it was right to begin the university in the city it is right to continue it there as long as a majority of the trustees think proper. He states, what is generally accepted as a fact, that Clifton is at present too unhealthy on account of malaria for the site of a university, and that to bring the grounds into a healthy condition, and erect there the buildings necessary for conducting such an institution, which under the will would have to be done from the income, would involve sufficient expense to cripple the university, and degrade it from a first-class university to a second-class college. Whereas if there was one thing about which the intentions of Johns Hopkins were clearly expressed, both in and out of his will, it was that the institution founded by him should be a university.

In answer to Mr. Garrett's question, "What has the university done?" Judge Brown replies that "it has attained to an acknowledged rank among the best institutions of this country as a place for the advancement of knowledge or the education of scholars. . . . It has established laboratories of chemistry, physics, and biology where some important discoveries have been made, and great facilities have been given for the study of those sciences. It has published seven serial publications for philology, mathematics, chemistry, biology, physiology, history, and for general information. . . . By its fellowships it has been the means of training ninety young men, of whom fifty-five have

attained good positions as teachers in colleges and kindred establishments, and twenty-three are still resident here. It has taught 535 students, of whom over 100 are known to have taken honorable stations as teachers in such institutions as Harvard, Princeton, Cornell, Lafayette, the 'universities of Virginia, North Carolina, Louisiana, Michigan, and several other colleges and universities.' 'It has given Hopkins Scholarships to eighty-five young men. It has attracted during the year advanced students from more than sixty other institutions,' and 'has a very far larger number of advanced students than any college or university in the United States, more, I believe, than all together. . . . It has given ninety courses of lectures by eminent men on a great variety of subjects to which the public have been admitted gratuitously. It has collected a library of 17,000 volumes and scientific instruments which have cost about \$50,000."

These and many other important things Judge Brown shows that the university has done, and cites an anonymous writer in "the journal called *Education*," who claims that "all strong colleges will follow the example of Baltimore." He further calls attention to the undergraduate department of the university, in which "seven courses have been prepared with great care for the wants of those intended for different colleges, all tending to the same academic degree." Mr. Garrett's attractively-sounding plan for the "wise utilization" of "the vast and splendid estate of Clifton" Judge Brown characterizes as "a vague and fanciful sketch," and shows that for its accomplishment the university would be starved for want of means, and become practically useless.

With regard to the speedy opening of the hospital he says, "It is the object of the board to make the hospital the most complete in the world, and I believe they will succeed in the attempt. To accomplish this extraordinary pains have been taken and expense has not been spared. It would be bad economy to retard the completion of so noble a work by a premature and partial opening."

It may seem a little peculiar to some of the readers of the *JOURNAL* that a trustee should pursue such a course as has Mr. Garrett towards his fellow-trustees. Judge Brown certainly so regards it, and in the conclusion of his letter speaks of it in the following way:—

"As differences of opinion necessarily arise in every board the rule of law is that in all questions on which it is required to vote the majority must prevail, and, therefore, the minority must submit. If in the opinion of the minority the majority has by its vote violated legal obligations, then it is the right of the minority to apply to the courts for redress. Here the law ends, but there is a well-settled rule of decorum which forbids that a dissatisfied member should bring his grievances before the public, and assail his associates in speeches and newspaper articles."

It is devoutly to be wished that this letter may end the controversy, and the university be allowed to pursue the "even tenor of its way;" unfortunately, however, this does not seem likely to be the case.

I may add in conclusion that the university held its seventh annual commencement on the 7th of this month, and President Gilman has sailed for Europe, partly for pleasure and partly on business connected with the medical school.

Very respectfully,

B.

REPORTED MORTALITY FOR THE WEEK ENDING JUNE 16, 1883.

Deaths reported 2239 (no reports from Chicago, New Orleans, and District of Columbia): under five years of age 849; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 485, consumption 333, lung diseases 191, diarrhoeal diseases 122, diphtheria and croup 112, scarlet fever 83, measles 62, typhoid fever 28, cerebro-spinal meningitis 21, malarial fevers 17, erysipelas 14, puerperal fever 11, small-pox nine, whooping-cough six. From *measles*, New York 19, Boston 14, Brooklyn five, Cambridge four, Philadelphia four and Baltimore three each, St. Louis, Pittsburg, Nashville, and Lynn two each, Buffalo, Salem, Somerville, and Haverhill one each. From *typhoid fever*, Philadelphia nine, Boston four, New York three, Brooklyn, St. Louis, Baltimore, Pittsburg, Buffalo, Providence, New Haven, Nashville, Lowell, and Westborough one each. From *cerebro-spinal meningitis*, New York and Milwaukee four each, Buffalo three, Philadelphia two, St. Louis, Cincinnati, Providence, Charleston, Worcester, Lynn, Somerville, and Holyoke one each. From *malarial fevers*, New York six, St. Louis three, Brooklyn and Baltimore two each, Charleston, Nashville, Springfield, and Westfield one each. From *erysipelas*, New York five, Cincinnati and Lynn two each, Philadelphia, Brooklyn, Buffalo, Lowell, and Newburyport one each. From *puerperal fever*, Philadelphia and Boston two each, New York, Brooklyn, St. Louis, Buffalo, Milwaukee, Providence, and Taunton one each. From *small-pox*, St. Louis five, Philadelphia and Nashville two each. From *whooping-cough*, New York two, Philadelphia, St. Louis, Baltimore, and Lynn one each.

Twenty-four cases of small-pox were reported in St. Louis, Baltimore one, Boston one; measles 141, scarlet fever 32, diphtheria 24, and typhoid fever six in Boston; scarlet fever 16, and diphtheria 11 in Milwaukee.

In 37 cities and towns of Massachusetts, with an estimated population of 1,110,664 (estimated population of the State

1,922,530), the total death-rate for the week was 21.06 against 19.18 and 19.66, for the two previous weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending June 2d, the death-rate was 19.4. Deaths reported 3212: acute diseases of the respiratory organs (London) 246, measles 98, whooping-cough 78, scarlet fever 62, fever 52, diarrhoea 42, diphtheria 24, small-pox (London two, Liverpool, Hull, and Newcastle one each) five. The death-rates ranged from 13.1 in Brighton to 26.9 in Hull; Sunderland 15.5; Birmingham 16.7; Plymouth 17.4; Leicester 18.1; London 18.5; Sheffield 20.3; Leeds 22.9; Liverpool 25.1; Manchester 25.2. In Edinburgh 21; Glasgow 27.4; Dublin 31.8.

For the week ending May 26th, in 169 German cities and towns, with an estimated population of 8,659,662, the death-rate was 26.8. Deaths reported 4464; under five years of age, 1078; consumption 691, lung diseases 580, diarrhoeal diseases 157, diphtheria and croup 153, measles and röteln 97, scarlet fever 67, whooping-cough 47, typhoid fever 38, puerperal fever 13, small-pox (Breslau two, Beuthen, Gortitz, Bremen, Cologne Achen, and Frankfurt a. M. one each) eight, typhus fever (Königsberg, Bromberg, Leipzig, and Braunschweig one each) four. The death-rates ranged from 18 in Wiesbaden to 40.3 in Würzburg; Königsberg 32.3; Breslau 30.5; Munich 32.1; Dresden 26.3; Berlin 28.4; Leipzig 24; Hamburg 28; Cologne 29; Frankfurt a. M. 25.4; Strasburg 27.3.

For the week ending June 2d, in the Swiss towns, there were 32 deaths from consumption, diarrhoeal diseases 17, lung diseases 15, measles 12, diphtheria and croup six, whooping-cough four, erysipelas three, scarlet fever two, typhoid fever one. The death-rates were at Geneva 15.4, Zurich 8, Basle 23, Berne 27.1.

The meteorological record for the week ending June 16th, in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

Deaths reported 2293 (no reports from New Orleans, District of Columbia, and Charleston): under five years of age 994: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 565, consumption 270, lung diseases 187, diarrhoeal diseases 214, diphtheria and croup 107, scarlet fever 72, measles 52, typhoid fever 29, cerebro-spinal meningitis 26, malarial fevers 22, whooping-cough 19, puerperal fever eight, erysipelas seven, small-pox six, typhus fever three. From *measles*, New

York 19, Boston eight, Baltimore seven, Philadelphia and Pittsburg four each, Brooklyn three, Cincinnati, New Haven, Nashville, Springfield, Salem, Newton, and Westfield one each. From *typhoid fever*, New York eight, St. Louis five, Philadelphia and Chicago four each, Brooklyn and Pittsburg two each, Baltimore, Cincinnati, Buffalo, and Somerville one each. From *cerebro-spinal meningitis*, New York eight, Chicago six, Springfield three, Milwaukee two, Philadelphia, St. Louis, Providence, Lowell, Holyoke, Haverhill, and Weymouth one each. From

malarial fevers, New York 10, Chicago and New Haven three each, Philadelphia and Brooklyn two each, St. Louis and Baltimore one each. From *whooping-cough*, New York eight, Chicago five, Philadelphia three, Brooklyn, St. Louis, and Lynn one each. From *puerperal fever*, Cincinnati two, New York, Chicago, Boston, St. Louis, Cambridge, and Salem one each. From *erysipelas*, New York three, Brooklyn, Pittsburg, Milwaukee, and Cambridge one each. From *small-pox*, St. Louis three, Philadelphia two, Baltimore one. From *typhus fever*, Philadelphia three.

Nineteen cases of small-pox were reported in St. Louis, Baltimore three, Boston one, Buffalo one; measles 81, diphtheria 24, scarlet fever 21, typhoid fever eight in Boston; scarlet fever five, and diphtheria one in Milwaukee.

In 39 cities and towns of Massachusetts, with an estimated population of 1,169,950 (estimated population of the State 1,922,530), the total death-rate for the week was 16.97 against 21.06 and 19.48, for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending June 9th, the death-rate was 19.5. Deaths reported 3223: acute diseases of the respiratory organs (London) 226, measles 139, scarlet fever 73, whooping-cough 61, diarrhoea 58, fever 34, diphtheria 28, small-pox (Newcastle four, London three, Liverpool

one) eight. The death-rates ranged from 14.7 in Bristol to 28.4 in Blackburn; Cardiff 16.8; Leeds 17.5; Birkenhead 18.2; Birmingham 18.4; London 18.5; Leicester 18.5; Manchester 22; Sunderland 22.8; Liverpool 25.5. In Edinburgh 17.9; Glasgow 33.9; Dublin 28.3.

For the week ending June 2d, in 168 German cities and towns, with an estimated population of 8,641,299, the death-rate was 26.8. Deaths reported 4457; under five years of age, 2145; lung diseases 652, consumption 635, diarrhoeal diseases 214, diphtheria and croup 135, measles and röteln 111, scarlet fever 56, typhoid fever 50, whooping-cough 48, puerperal fever 18, small-pox (Bremen two, Heilbronn one) three, typhus fever (Stettin one) one. The death-rates ranged from 14.7 in Wiesbaden to 35.7 in Kiel; Königsberg 30.4; Breslau 28.4; Munich 33.2; Dresden 25.4; Berlin 32; Leipzig 20.4; Hamburg 28.3; Cologne 28; Frankfurt a. M. 24.7; Strasburg 30.6.

For the week ending June 9th, in the Swiss towns, there were 26 deaths from consumption, lung diseases 24, diphtheria and croup 10, diarrhoeal diseases eight, scarlet fever four, measles three, whooping-cough one, puerperal fever one. The death-rates were at Geneva 11.3, Zurich 10, Basle 19.1, Berne 24.6.

The meteorological record for the week ending June 23d, in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

HARVARD MEDICAL SCHOOL.

At the annual commencement of Harvard University the following students received the degree of Doctor of Medicine:—

FOUR YEARS' COURSE.

Franklin Asaph Dunbar, A. B.
 Harry Madison Cutts, A. B.
 Samuel Delano, A. B.
 Francis Xavier Dervin.
 Fred William Kennedy.
 William Henry Devine.
 Philip Coombs Knapp, A. B.,
 Michael Ricard Donovan, A. B.,
cum laude.
 Asbury Gilbert Smith.
 Charles Stein Dunn.
 Edward Winslow Warren, A. B.
 Harry Winthrop Faulkner.
 Patrick Joseph Finnigan, A. B.
 Henry Austin Wood, A. B.,
 Charles Chauncy Foster, A. B.,
cum laude.

THREE YEARS' COURSE.

Albert Clinton Aldrich, A. B.
 Clarence Miles Godding, A. B.
 Bradford Allen, S. B.
 Arthur George Griffin.
 Louis Edmund Allen, A. B.
 Charles Henry Grimm.
 Charles Augustus Atwood.
 Ramon Benjamin Guitéras.
 David Erastus Baker, B. S.
 William Dudley Hall, A. B.
 Frederic Melancthon Briggs,
 George Haven.
 A. B.
 Parke Woodbury Hewins, A. B.
 Fred Alpheus Chandler.
 Andrew Hall Hodgdon, A. B.
 Clarence Alonzo Cheever, B. S.
 Charles Sumner Holden.
 A. S.
 Frank Holyoke.
 Adam Stuart Muir Chisholm.
 Rufus Peabody Hubbard.
 Henry Tisdale Coggeshall.
 George Wood Huse, A. B.
 Charles Hale Cogswell, A. B.
 Alton Atwell Jackson.
 Ralph Marcus Cole.
 Frank Mackie Johnson, B. S.
 Joseph Daniel Couch.
 Herbert Shattuck Johnson,
 A. B.
 Thomas Edward Cunningham.
 Lawrence Grafton Kemble.

Freeman Alexander Mackenzie.

Francis Coffin Martin, A. B.
 Rufus Cyrene McDonald.
 William Henry McOwen.
 Joseph Briggs Murphy.
 Henry Sharwood Otis.
 James Cogswell Dumaresq
 Pigeon, A. M.
 Wallace Preble, A. B.
 George Edward Richards, A. B.
 Frederick Jerome Ripley, A. B.
 Charles Dexter Sawin, S. B.
 Columbus Sewell Scofield.
 Charles Edward Simpson.

Hayward Stetson, A. B.
 William Caldwell Stevens, A. B.
 William Stanford Stevens, A. B.
 Benjamin Ropes Symonds.
 William Allen Tremaine.
 John Trumbull, A. B.
 Charles Everett Warren, A. B.
 Charles Edward Webster.
 James Lee Wells, A. B.
 Arthur Bryant Wetherell.
 Leonard Darling White.
 Roland Barker Whitridge.
 Walter Woodman, A. B.
 Alfred Worcester, A. M.

The name of Lester Sackett Ford, B. A. S., is to be placed in the quinquennial catalogue with the class graduating this year, his death having taken place after all the examinations required for the degree had been passed.

The degree of Master of Arts was conferred on the following students of the four years' course: Franklin Asaph Dunbar, A. B., Philip Coombs Knapp, A. B., Edward Winslow Warren, A. B., Henry Austin Wood, A. B.

CORRECTION.

MR. EDITOR, — The following correction should be made on page 558 of the Boston Medical and Surgical Journal of June 14, 1883. In the table of Analyses of Infant Foods, opposite Mellin's Food, and under Starch, the "4" is a misprint for "—." As is well known this food contains no starch.

Yours truly, B. F. DAVENPORT.

THEORIES REGARDING THE MECHANISM OF THE INORGANIC CARDIAC MURMURS¹

BY G. M. GARLAND, M. D.,

Assistant in Clinical Medicine, Harvard Medical School.

ANÆMIC MURMURS.

ALMOST immediately with the discovery of cardiac murmurs and their association with valvular deficiencies of the heart it was likewise discovered that murmurs in the cardiac region are not all referable to such deficiencies of the valves. As early as in the twenties of this century, and especially during the thirties, we find evidence, clinical and post mortem, rapidly accumulating to prove the existence of five distinct groups of præcordial murmurs:—

(1.) Murmurs associated with organic alterations of the cardiac orifices. *Organic murmurs.*

(2.) Murmurs accompanying anatomical defects in the development of the heart. *Congenital murmurs.*

(3.) Murmurs which are temporary in duration, which occur during certain fevers and constitutional conditions, but disappear on restoration of health.

(4.) Murmurs which are observed before death, but for which no anatomical explanation is discoverable after death. *Inorganic murmurs.*

(5.) Murmurs which are produced by pathological changes in the various tissues immediately surrounding the heart, pericarditis, pleuritis, aneurism, pressure on large vessels from tumors, or solidified lung, cardiac respiration, etc. *Pseudo-cardiac murmurs.*

The first two groups and the last one have been ably treated by my friend, Dr. Shattuck, this evening, and, therefore, I propose to speak only of the history and present status of the theories regarding the third and fourth groups.

With the announcement of the fact that blood murmurs may occur in the region of the heart without the presence of any organic lesion of that organ a violent warfare broke out among authorities as to the seat of those murmurs. Each cardiac orifice in turn was accused of producing *murmurous* riot, while each in turn was denied any participation in the same. It was early and generally allowed that these murmurs are *systolic* in rhythm,² and the strife regarding their location was gradually narrowed down to the following theorems:—

Hope and his followers in the English school maintained that inorganic murmurs are produced exclusively at the aortic or pulmonic orifices, and are audible only at the base of the heart.

Stokes and his followers in Dublin maintained with equal vehemence that they had heard murmurs at the apex which were temporary in duration, and yet at post mortem no disease of the cardiac valves was discoverable.

The feeling between the two schools on this topic was very bitter, and Stokes complained in a private letter to a friend that Hope had injured him in a case cited by giving an opposite opinion regarding an apex murmur.

Since those days, however, the gradual accumulation of evidence has gone to show that inorganic murmurs

may be heard at the apex as well as at the base of the heart. While it is true that an intra-cardiac murmur at the apex of the heart, as a rule, indicates mitral disease, yet such murmur may be independent of anatomical changes in the mitral or tricuspid valves.

At present the inorganic murmurs are divided into two groups, as follows:—

(1.) Murmurs which are audible only at the base of the heart.

Such murmurs occur in typical form with chlorosis, and are called *hæmic murmurs*.

(2.) Murmurs which are heard at the apex.

This group appears during chorea, and are called *dynamic murmurs*.

These groups differ essentially in the interpretations which have been applied to them, and, therefore, we will consider them separately, beginning with the basic or

Hæmic Murmurs. Next in importance to the warfare over the location of these murmurs has been the strife over their interpretation and over the explanation of their origin. Many of the theories at first advanced were purely imaginative, and grossly opposed to well-known physical laws. As in the history of all natural phenomena which have attracted man's attention the early explanations have been purely speculative theories, and only at later periods, when the rules of scientific methods were applied, have we obtained any reliable working hypotheses. Such has been the history of hæmic murmurs. It is much easier to speculate than to investigate.

It would consume too much space to quote at length from all the authors who have attempted to illumine this topic, and, as may be seen below, the mere enumeration of their theories makes quite a formidable list:—

Spasm of the vessels (Laennec). Friction of blood against the arterial wall. Density of the blood. Velocity of the blood. Tension of the vascular walls. Vibrations of the vascular walls. Folds of the inner coat of the artery (Vernois). High blood tension (Beau). Low blood tension. Constriction of artery. Presstrahl (Niemeyer). Prolongation of the first heart sound behind the sternum (Monneret). Spasmodic contraction of the cardiac orifices causing obstruction to the blood currents (Andral). Diminished tension of the blood alters the swinging of the valves, and allows the valve-tips to lie over each other in systole. Twisting of the aorta (Marey). Twisting of the pulmonary artery (Nixon). Vibrations of the mitral valves transmitted along the wall of the pulmonary artery (Meyer). Density of the blood (Bouilland).

The first theory which attained to any extended following was that of the friction of the blood against the vascular walls, and this was warmly championed by so able a knight as Skoda. Vernois sought to strengthen it by supposing that the friction is increased by projecting folds of the arterial wall, a condition of things which, it is needless to say, has never been observed, and is merely imaginative.

The friction theory, however, was soon proven wrong by the researches of Kiwisch, Chauveau, and Helmholtz, who showed by experiments in physics that no friction is possible between a fluid and its containing tube so long as the fluid is capable of wetting the surface of the tube.

Then arose the theory of *inter-molecular friction*, which was expressed by Leared in 1852, that the soufflé is due to a reciprocal pressure of the particles of the circulatory fluid, from which results that the primordial current is divided into secondary currents,

¹ Read before the Suffolk District Medical Society, April 28, 1883.

² Three cases of diastolic functional murmurs have been reported. See Dr. Shattuck's article in this number of the JOURNAL.

and the molecules instead of preserving a uniform relation in their movement acquire a new and irregular impulsion.

In order to more clearly understand this inter-molecular theory it will be necessary to understand certain experiments made upon water flowing through tubes. It was found that no murmur is produced when water flows quietly through a tube of uniform calibre. If the water be forced along with great velocity a murmur will be heard. Again, if a constriction in the lumen of a tube be produced at any point a murmur will be audible beyond the constriction at a much less velocity of the water. The passage of the fluid through a narrow strait into a wider basin causes a series of "eddies" and counter-currents, which, by their mutual friction, produce sound.

Now it was obvious that the blood does not, ordinarily at least, flow with sufficient velocity to produce a murmur under the conditions given for a tube of uniform calibre, hence the claim of vascular constrictions, either at the cardiac orifices or in the course of the veins and arteries, was advanced, and this formed the essence of Niemeyer's "*Pressstrahl*" theory. Moreover, to insure the necessary constriction of the tube numerous subsidiary theories were advanced, such as a supposed twist at the beginning of the aorta during systole (Marey); a twist at the root of the pulmonary artery (Nixon); a spasmodic contraction of the cardiac orifices (Andral). Such theories as these, however, regarding spasm and twist, are mere conjecture, and entirely destitute of experimental or anatomical proof. Constriction of the aorta or pulmonary artery will produce murmurs. This much we know. But that such constrictions occur rhythmically and intermittently with the action of the heart is too visionary for credence.

To seek escape from the dilemma presented by the apparent lack of constriction in the arteries mentioned, attention was directed to the condition of the blood itself. It is a notorious fact that basic and other vascular murmurs are most common with chlorosis, and that in this disease the blood is poor in quality. Accordingly some observers maintained that a watery condition of the blood was conducive to murmurs. Skoda opposed this idea vigorously, and declared that he had frequently sought for such murmurs after severe hæmorrhage, and never found them. Bouillaud, however, studied the subject more deeply, and measured the density of the blood in chlorotic cases, and he declares that the *bruit de diable* exists, as a general rule, in individuals whose blood has a less density than six degrees of the aréomètre of Beaumé, and does not appear so long as the density exceeds that figure. Then Williams, Weber, Nolet, and Richardson experimented on fluids forced through tubes, and declare that the ease with which murmurs can be thus produced stands in an inverse ratio to the density of the fluid, and when water is added to blood a murmur is elicited more easily than when blood alone is used. Richardson says: "It is now understood that fluids are not only conductors of sounds, but that they produce sounds under certain conditions. . . . If our blood were reduced to the condition of distilled water, and we could live and hear as we do now, we should, probably, always be conscious not only of the heart sounds, but of a soft, internal musical murmur, produced in our own vessels." Leared also shows that in order to obtain fluid friction the currents need not flow in opposite

directions. It is only necessary that one current be faster than the others.

It was long supposed that the blood tension in chlorosis was diminished, and those who talked about a twisting of the aorta and pulmonary artery all assumed and asserted such diminution of blood tension. Bamberger speaks of abnormal relaxation of pulmonary artery. Nixon speaks of "loss of arterial tonicity." Marey bled animals, and finding that such bleeding was followed by a murmur, attributed such murmur to low tension in the aorta. It has been well said, however, that if Marey's theory be correct we ought to hear a murmur in the aorta every time we have a diastolic pulse, but such is not the case.

Similar experiments upon the effects of bleeding were made by Beau, Vulpian, and Deschambre, and they all found that a hæmorrhage does not immediately produce a murmur. The first effect of bleeding is, of course, to empty the vessels and lower the blood tension. Immediately, however, the vessels begin to absorb water from the neighboring tissues, and thus rapidly renew the bulk of fluid which they lost. By this means the previous blood tension in the arteries is not only restored but even exceeded. At this stage we have a very high arterial tension combined with a watery condition of the blood, and it is then, according to Beau, that the so-called anæmic murmur is developed in veins and arteries. Moreover, this murmur lasts only as long as the blood tension remains high. If the tension be suddenly lowered by another hæmorrhage the murmur immediately disappears, and does not return until the condition of spanæmia or serous polyæmia, as Beau terms it, is restored by renewed absorption.

Besides this spanæmia and high arterial tension Beau found that the heart was hypertrophied and actually weighed more as a result of repeated hæmorrhages. Now the condition of the blood and arterial tension in chlorosis is very similar to that of the animals which were bled. Wunderlich, as far back as 1856, and Friedreich in 1867, described the chlorotic heart as dilated. Beau, Bamberger, and Stark, however, claim that the chlorotic heart is *hypertrophied* as well as dilated, and Heitler in a recent investigation speaks of the *dilated hypertrophy* of a chlorotic heart. Moreover, the second sound of the chlorotic heart is usually accentuated, which indicates high tension in the pulmonary artery, and therefore the evidence seems conclusive that the condition of chlorosis resembles the high tension and serous polyæmia of the animals experimented upon, and the murmur is attributed to the high tension of this attenuated blood.

In advanced stages of chlorosis we may have murmurs at the apex as well as at the base of the heart, but these will be spoken of in connection with the so-called dynamic murmurs.

To sum up our story, then, we find that experiments and clinical observation seem to harmonize in the following respects:—

- (1.) Local constrictions in a tube favor the production of murmurs in fluids flowing through them by causing eddies and molecular friction.
- (2.) The molecular friction of a fluid is greater and more productive of audible murmurs according as (a.) the velocity is greater, (b.) the density is diminished, (c.) the tension is increased.

Allowing that blood vibrations are capable of causing sounds, as I think we must allow from the evidence

given, the question naturally arises as to the participation of the vascular walls in the production or modification of the sounds which we hear. There are those who maintain that the sounds are due to the vibration of the walls themselves. Such views appear to me untenable, however, although I do believe that the vibrations of the blood may be and probably are materially modified by the walls which transmit them outward.

We never speak of the telephone as producing the sound waves which we listen to during an electrical conversation, but we do recognize that the vibrations which are peculiar to the transmitter do modify the conveyed speech, because we could instantly tell in the darkest room whether a person were talking to us through a telephone or through an ordinary speaking tube, for instance. Moreover, some transmitters are good and some are bad. Some are so bad that no voice comes through, and the degrees of efficiency depend upon the ability of the tympanum to take up and convey the vocal vibrations without destroying their rhythm.

In a similar manner I assume that the matter of our hearing the blood murmurs depends in a great measure upon the capacity of the arterial walls to vibrate in unison with the blood itself. Just how much or how little they contribute to the sound itself will probably remain a doubtful question for some time to come.

APEX MURMURS.

Dynamic Murmurs. The group of functional murmurs heard at the apex have been termed dynamic murmurs because they are supposed to be due to some temporary lack of cardiac force or to an irregular application of that force. The murmur which is often heard in chorea is taken as the type of this class, and in advanced stages of chlorosis there may be apex as well as basic murmurs. Many of these murmurs are temporary and disappear with the restoration of general health. Bristowe, however, reports cases in which there were clinical proofs of mitral incompetence, including pulmonary apoplexy, anasarca, and nutmeg liver, and yet at the autopsy the mitral valve and the orifice it protects were found to present a perfectly healthy appearance. Several cases are also referred to by Bristowe where he thinks the murmur was due to tricuspid regurgitation, but he adds: "It may almost be regarded as an axiom in medicine that the presence of a systolic murmur at the apex is a positive proof of regurgitation through the mitral orifice."

Under the head of dynamic murmurs, therefore, we have a wide group of phenomena extending from a simple temporary whiff without any obvious organic disturbance to a series of most disastrous casualties in lungs, liver, and kidneys. Balfour asserts, indeed, that a dynamic regurgitation produces the same results as an organic regurgitation if it persists long enough. It is obvious, also, that we have but two decisive means for differentiating between a dynamic and an organic murmur. If a murmur develops during any prostrating disease but ceases on the restoration of health it is declared to be dynamic. Should it persist, however, and develop sequelæ, the autopsy alone will distinguish it from a case of valvular destruction.

Stokes and Gairdner considered dilatation of the heart a frequent cause of an apex murmur, while Parrot believed the dynamic murmur to be always due to tricuspid regurgitation.

Eichhorst thinks many murmurs are due to innervation disturbances which render the closure of the valves irregular, and he adds that cases of relative valvular insufficiency soon lead to hypertrophy of the heart if they are not cured.

Walshe thought the choreic murmur was due to a sort of choreic, spasmodic action of the muscoli papillares, but it seems hardly probable that such a spasmodic action of these muscles would be so rhythmical as the choreic murmur is.

Bristowe offers the following conditions as explanations of an apex murmur with mitral orifice of normal size:—

(1.) Presence of coagula which form just prior to death.

(2.) Dilatation of the auriculo-ventricular opening.

(3.) Disproportion between the size of the ventricular cavities and the length of the chordæ tendinæ and muscoli papillares.

(4.) Lateral displacement of the origins of the muscoli papillares in consequence of the rounded form which dilatation imparts to the heart.

(5.) King's safety-valve action of the tricuspid. When the blood tension becomes high the tricuspids will often leak, and thus take off from the lungs a portion of the high-pressure strain.

The theory of temporary dilatation of the mitral orifice, combined with a parietal debility of the left ventricle (Hayden), has received quite general support, and has recently been presented in a somewhat new form by Donald McAllister, who bases his conclusions upon some experiments of Ludwig and Hesse regarding the movements of the heart. Ludwig and Hesse succeeded, by an ingenious method, in obtaining plaster casts of the heart during complete systole and again during diastole. By comparing these casts two points are noticeable: first, the heart shortens but little if any during systole; second, the transverse axis at the base of the ventricles is diminished nearly one half during systole. This means that during contraction of the heart the transverse area of the base of the ventricles becomes only a little more than one half its size in diastole. Now this diminution of area falls in the plane of the auriculo-ventricular orifices, and consequently the size of these orifices being actually reduced nearly one half during systole, the valve curtains are able to fill them up and prevent regurgitation. Supposing, however, that the cardiac muscles are weak, or the blood tension is very high, so that the orifices named are imperfectly contracted, then the valves will prove insufficient and regurgitation will result. This regurgitation is not due to a dilatation of the orifice beyond its normal anatomical limits, but to an incompetent contraction during systole, and thus at post mortem the orifice and valves appear perfect.

—The *Medical Times and Gazette* says that the adulteration of food has not escaped attention by the authorities even in Spain, and mentions the following original method of one Spanish magistrate in dealing with sophisticated articles: "All articles," runs a proclamation, "in the shape of wines, groceries, and provisions, which upon examination and analysis are proved to be injurious to health, will be confiscated forthwith and distributed to the different charitable institutions."

THE DIAGNOSIS OF THE SO-CALLED "FUNCTIONAL MURMURS."¹

BY F. C. SHATTUCK, M. D.

IN the second edition of his great work on diseases of the chest, in discussing the cause of cardiac and arterial murmurs, Laennec speaks as follows: "I have known a considerable number of persons die of different diseases, acute or chronic, who had presented this phenomenon (murmur) very distinctly during the latter part of their life, sometimes during several months, as well in the heart as in different arteries, and upon the examination of whose bodies I could discover no organic lesion coinciding constantly with these phenomena, and which are not frequently met with in subjects who had never exhibited anything of the kind during life. In the first edition of this work I considered the bellows-sound of the heart as an indication of the contraction of the orifices. No doubt it exists almost always in this case, but since the first publication of my treatise I have very frequently met with it in individuals who had no lesion of the sort, while on the other hand I have seen ossifications of the valves which were not attended by this sound. . . . In like manner I can state with certainty that the bellows-sound of the heart is very often met with when this organ is perfectly healthy."²

Laennec thus recognized the fact that a murmur is not sufficient evidence on which to base a diagnosis of organic change in the heart or its valves, and, in view of his premature death, it is not to be wondered at that he could but very imperfectly practically apply the fact to the clinical distinction between murmurs which are serious and those which are not. "The sole disorder," he says, "which has appeared to me constantly, or almost constantly, to accompany the bellows-sound is a state of nervous agitation more or less marked;"³ he also noticed that a murmur is produced over an artery when pressure was exerted upon it by the finger or stethoscope, though he failed to see that the pressure is the direct cause of the murmur, but attributes all these murmurs to spasm of the heart or arteries.

Very few of the modern writers on cardiac disease and the physical exploration of the chest with whose works I am acquainted seem to me to be sufficiently explicit in the directions which they give for making this practical distinction, the great importance of which is obvious.

Valvular disease involves more or less disability for life, a disability varying in degree with the character and extent of the disease, the age of the patient, the completeness of the compensation, and last, though, perhaps, not least, the ability and willingness of the patient to avoid overtaxing his heart in any way, and at the same time shun causes of anæmia and debility, which tend to produce relaxation and dilatation of the cardiac walls, and thus impair the compensation.

A person who is so situated that he can live on a level with his heart may perfectly well reach advanced old age, although the valves are somewhat damaged and no life company will insure him. But economy he must practice, having no longer the surplus heart power which belonged to him while the organ was

still structurally unimpaired. Moreover, no sooner does a patient learn that there is trouble with his heart than visions of sudden death are only too apt to rise before him. He often sees in the newspapers paragraphs announcing that some one has expired suddenly in the street, at his place of business, in a public conveyance, and that the "death is attributed to heart disease." In no other class of affections does the sword appear to the public eye suspended by so slender a thread. The profession holds much sounder views as to the compatibility of organic lesions of the valves with longevity than it did formerly, and in time these views will filter down to the general public. But meanwhile it behooves us to be very careful not to be guilty of the disservice of allowing persons with murmurs, but sound hearts nevertheless, to think themselves the subjects of valvular disease.

Dealing with this subject from an exclusively clinical point of view I would include all cardiac murmurs in two grand divisions:—

I. Those dependent on organic and permanent changes, especially in the valves of the heart, commonly called "organic" murmurs.

II. Those not so dependent, and commonly called "functional" or "inorganic" murmurs.

The vexed and very interesting question of the mechanism of this second class of murmurs does not come within the scope of my paper, so I pass on to the conditions under which they occur.

These "functional" or non-serious murmurs are met with

- (1.) In anæmia.
- (2.) In adynamic fevers and chorea.
- (3.) Connected in some way with respiration, the pseudo or respiratory murmurs.
- (4.) Mitral definite connection of any kind.

(1.) The anæmic murmurs, as their name indicates, are associated with an impoverished condition of the blood from any cause. They are systolic in time, are heard chiefly at the base, and then usually to the left of the sternum in the pulmonic area, though they may also be heard, but with diminished intensity, at the apex. They are apt to be accompanied by venous hum in the veins of the neck, and are said to be louder in the recumbent than in the erect posture.

(2.) In fevers of any kind attended by severe prostration, and also in chorea, a systolic murmur is often developed about the heart; this murmur is, as a rule, loudest at the apex, and is sometimes heard only at or in the immediate neighborhood of that region.

(3.) The respiratory or pseudo murmurs may be heard in any portion of the cardiac area, are nearly always systolic in time, and disappear or are greatly modified in character when the breath is held, sometimes at the end of inspiration, sometimes of expiration. Most of them seem to depend on the effect of the cardiac movement on the air contained in thin-walled pulmonary cavities bordering on the heart, or on solidification or retraction of that portion of lung which normally overlies or touches the heart, but they sometimes occur when no change in the pulmonary tissue can be surely detected, at least during life. They are analogous to the subclavian systolic whiff so often heard as well in individuals who are apparently healthy as in those suffering from infiltration of or pleurisy about the apex of the lung.

- (4.) One meets with some murmurs at the apex, as

¹ Read before the Suffolk District Medical Society, April 28, 1883.

² Forbes' Translation, page 558. London: Underwood. 1837.

³ Page 560.

well as at the base, unassociated with anæmia, chorea, fever, accentuation of the pulmonic second sound, phases of the respiratory process, changes in the lungs, or any previous history of rheumatism, which, from the practical point of view of prognosis and treatment, I class as functional, for the reason that months after they were first observed they remain the sole evidence of any inadequacy of the heart for its work.

For this classification I do not claim absolute completeness, but think that it will be found to include all the non-serious cardiac murmurs which are not extremely rare.

We now come to the clinical distinction between these murmurs and those which are serious, organic, incurable, and involve disability.

This distinction involves their consideration

- (a) As to rhythm.
- (b) As to associated conditions.
- (c) As to persistency.
- (d) As to time of propagation.
- (e) As to enlargement of the heart.

(a.) Functional murmurs are almost always systolic in time. Some authorities allow no qualification, but later writers are more cautious, and rightly so in view of the three cases, with autopsies, reported by Weiss,¹ who also alludes to a few observed by others. A practical deduction is that diastolic murmurs are almost always invariably organic.

(b.) The association of anæmia, adynamic fever, chorea, and phases of the respiratory process or lung changes require merely mention.

(c.) The murmurs belonging to the above conditions are not persistent except occasionally that of chorea. In anæmia and fever the murmurs disappear with the restoration of the general health, and the pseudo murmurs are characterized by their dependence on respiration or changes in the lungs. Organic murmurs may, it is true, disappear for a time from feebleness in the power of the cardiac contraction, or other cause, but their sequence, enlargement of the heart, does not disappear with them.

(d.) Functional murmurs have no definite line of propagation, the basic into the carotids, as in aortic obstruction, the apical toward the axilla or round to the back, as in mitral regurgitation. They are pretty closely limited to the cardiac area, and are very rarely, if ever, to be heard at the lower angle of the scapula. It must, however, be confessed that the mere loudness of a murmur is no safe index of its gravity.

(e.) We now come to the point of all others the most important, that, namely, of enlargement of the heart. Whenever obstruction or regurgitation at an orifice is in the least marked or has lasted a little time the normal balance of the circulation is disturbed and can be restored only in one way, by an increase in the size and power of the heart, such increase predominating in that portion of the organ on which the bulk of the extra work is thrown. This is what is meant by compensation. Thus, in aortic disease, the extra work being primarily thrown on the left ventricle this must increase in size and power to compensate the lesion; in mitral disease the heightened resistance in the pulmonary circuit involves like changes in the right ventricle. If compensation is not established the heart must soon fail; if it is established the sole means is through enlargement, in which hypertrophy predominates over dilatation, and this enlargement must, generally speak-

ing, be directly proportional to the extent of the lesion. Thus in either case we are not left long in doubt. Here, it seems to me, lies the kernel of the whole question. Whether regurgitation through the mitral orifice is the true cause of the murmurs of anæmia and the adynamic fevers as well as of any and every systolic souffle at the apex of the heart; whether this regurgitation be due to relaxation of the heart alone, as is maintained by McAlister, or to relaxation and a slight degree of enlargement, as is maintained by Balfour, these questions are of no material importance from a purely clinical standpoint, though of course from the points of view of physiology and pathology they are highly important and most interesting.

As regards prognosis and treatment a murmur, even if persistent, is of no importance to the patient unless it either is or, after a reasonable time, say six months if you choose, becomes associated with other well-marked evidences of a disturbance of the balance of the circulation, above all enlargement of the heart in some or all of its divisions.

But it is necessary to say one word more on this matter of enlargement. There seems to be little or no room for doubt that in anæmia and fevers of some severity or duration a certain relaxation of the cardiac muscle results from the impaired nutrition, and that in consequence of this the heart becomes somewhat dilated and therefore enlarged. It is, however, my belief that this enlargement is rarely sufficient to be manifested by physical signs indicating that condition. In anæmia the second pulmonic sound also is apt to be accentuated, but the very existence of the anæmia will prevent us from attaching too much importance to that fact, which, in the absence of such a condition, and provided always that the accentuation is real and not simply apparent, the aortic second being weakened or the lung tissue about the pulmonary artery being condensed or retracted, should always put us on our guard as to the presence of mischief.

It should be added, in passing, that a person, notably a young girl with menstrual irregularity, may be anæmic although the cheeks are flushed and the lips of a deep red. The pale, large, and indented tongue and the clammy hands and feet tell the true story.

Balfour finds the murmur of anæmia as a rule loudest an inch and a half to the left of the sternal border in the second interspace, over the seat of the left auricle. Since I became acquainted with his writings I have examined many cases with reference to this point, and my experience coincides with the almost universal teaching that the point of maximum intensity is usually just to the left of the sternum in the second interspace or over the third left costal cartilage.

To sum up. The true cause of cardiac murmurs, especially those ordinarily called "functional," not being fully understood, for practical purposes we need a practical classification. Clinically, then, we may divide murmurs broadly into the serious and non-serious, terms which do not especially please me, and which I am ready to abandon at any moment for others more descriptive and equally concise. Even if we include in the latter group some murmurs which are truly organic it seems to me that we do no harm, inasmuch as an injury to a valve which is so slight as to be followed by no other evidence of disturbance of the circulation after the lapse of six months or a year cannot be of any consequence.

¹ Wiener Wochenschrift, 1880, pages 137 and 160.

The differential diagnosis may be tabulated thus :—

THE SERIOUS MURMURS	THE NON-SERIOUS MURMURS
Occur at any time in the cardiac revolution.	Are systolic in time.
Are apt to be associated with rheumatism or its history.	Are usually associated with anæmia, fevers, chorea, or respiration.
Have definite lines of propagation.	Have no definite line of propagation.
Are persistent.	Are usually transitory.
Involve well-marked enlargement of the heart.	Involve no marked enlargement of the heart.

A NEW INTERPRETATION OF FLINT'S MITRAL DIRECT OR PRESYSTOLIC MURMUR WITHOUT MITRAL LESIONS.¹

BY A. T. KEYT, M. D., CINCINNATI, OHIO.

FLINT describes an interesting auscultatory phenomenon, namely, the occurrence of a cardiac murmur preceding and running into the first sound without mitral lesions, but always in association with considerable aortic insufficiency. He speaks of the murmur as *blubbery* in quality, best heard within the apex, and characterizes it as a *presystolic* or *mitral direct murmur*.

Although this murmur, it appears, has been recognized and pointed out alone by Flint, the correctness of the observation is not to be questioned. Discussion, however, is allowable regarding its interpretation and mechanism of production.

As just stated, our distinguished master refers the murmur to the mitral orifice, and terms it *presystolic*. The following is his explanation: "The left ventricle is filled with blood from the current passing from the auricle to the ventricle through an unobstructed orifice by gravitation, and, in addition, the regurgitant current from the aorta. As a consequence the mitral curtains are floated away from the ventricular walls and are not only approximated but in actual contact. These conditions existing, the auricle contracts and forces an additional quantity of blood into the ventricle. The mitral direct current passes between the valvular curtains which are in apposition, and throws them into vibration." Is the explanation sufficient? It would seem the segments would not arrange themselves in apposition because to do so would require a superior pressure on the ventricular side and the creation of a retrograde current towards the auricle. The fact is that during ventricular diastole the current is towards the ventricle, or possibly at a stand-still in the last moment before the occurrence of auricular systole. It is not conceivable that a retrograde current in the mean time could be established to close the segments, and from the first moment of auricular contraction the direct current would keep them well open. The experiment of injecting water through the mitral orifice into the ventricle, and proving that the valve becomes closed, succeeds only because a brisk retrograde current carries the curtains into apposition. The conditions are not analogous to those of the living mechanism.

But even if we could conceive of the valve as closed in the manner assumed the conditions would not yet be present for the production of a *presystolic*

murmur. The curtains would be limp and passive and awayed noiselessly apart as the blood under the auricular systole passed between them into the ventricle. They would lack the requisite tension or stamina to permit of their being thrown into sonorous vibrations by the action of the passing current.

For these reasons the theory offered by Flint does not appear to us adequate to explain the phenomenon of a cardiac murmur before the first sound in aortic insufficiency without lesion of the mitral valve.

We will now proceed to give what we conceive to be the true explanation.

In normal cardiac action the first sound of the heart is heard a notable time after the beginning of ventricular systole. This is readily demonstrated by employing a cardiograph and stethoscope at the same time and giving attention to the play of the lever and sounds of the heart. It will be observed that the lever has nearly or quite completed its ascent when the first sound impresses the ear. The time of this ascent marks the interval between the beginning of ventricular systole and event of the first sound. The interval is measurable and may be stated roundly at about one fifteenth ($\frac{1}{15}$) of a second, which is long enough for a practiced ear to appreciate.

Now, when the valves are perfect, the blood begins to escape from the ventricle through the aortic orifice about the time of culmination of the first sound, and a murmur generated at the aortic orifice would be heard with and following the first sound. This murmur would be counted, and truly, strictly systolic. But when the aortic valves are permanently open the blood would begin to flow through them immediately upon the beginning of ventricular contraction: the consequence would be the generation of a murmur which would begin before and run into the first sound. This murmur, though also in reality strictly systolic, would strike the ear as occurring before the beginning of systole because antedating the first sound of the heart.

Ventricular systole is an event which measures on an average .326 of a second, while the first sound of the heart, as appreciated by the ear, is of momentary duration. The first sound divides systole into a short anterior and longer posterior portion. The distinction here stated is not found in any of our classical works on the heart; nor have any of our distinguished auscultators, so far as known, recognized a chronometric difference between the beginning of systole and the first sound of the heart. Without this recognition a systolic murmur beginning before the first sound would of necessity be referred to the mitral orifice and distinguished as a mitral direct murmur. With this recognition opportunity is given for the localization of such murmur at the aortic orifice, and distinguishing it as an aortic direct murmur.

That the blood begins to flow through the aortic orifice in aortic insufficiency immediately upon the beginning of ventricular contraction, instead of after a notable interval, as when the valves are intact, has been distinctly demonstrated by the simultaneous graphic method. It has been determined that while in normal conditions the carotid pulse follows the systole of the ventricle at an interval of one twelfth second, in aortic insufficiency the interval may not be more than one thirty-second second.

If the scope of this article permitted we could produce here simultaneous traces, from both man and the schema, in demonstration of this interval when the

¹ American Journal of the Medical Sciences, July, 1862. The same, April, 1882. The London Lancet, American edition, April, 1883.

aortic valves are competent, and of its obliteration when they are open.

Under the cardiac conditions named all is favorable for the development and definition of systolic aortic murmur in antecedence of the first sound. The enlarged ventricle and hypertrophied walls would suddenly start a volume of blood through the altered orifice, engendering vibrations, while the closure of the expanded mitral valve would give smartness to the first sound, and so materially aid the differentiation of the latter from the murmur already in progress.

Evidently the "blubbery" quality attributed to this murmur could be produced at the aortic as well as at the mitral orifice; and it is not unusual for an aortic murmur to be well heard at or within the apex. In the cases cited by Flint, in the first, "at the apex was a presystolic blubbery murmur. At the base of the heart was an aortic regurgitant murmur which was diffused over nearly the whole præcordia." In the second case was found "an aortic direct and an aortic regurgitant murmur, both murmurs being well marked. There was also a distinct presystolic murmur within the apex, having the blubbery character." In a third case, recently reported, were four murmurs referable to the left side of the heart without mitral lesions. "The patient in this case had undoubtedly both a mitral systolic and a mitral presystolic murmur." In such a medley of sounds we appeal if it would be possible even for our author to decide that the murmur in question proceeded from the mitral orifice, independent of the preconception, that a murmur prior to the first sound is presystolic and necessarily mitral direct.

Other authorities, while accepting the soft presystolic murmur as signaling when present mitral obstructive lesion, do not admit the existence of a rough presystolic murmur under any conditions. The murmur under consideration they time as systolic. Flint likewise formerly considered it systolic. This goes to show how close must be this murmur to the first cardiac sound,—so close, indeed, that the superior and long cultivated ear of Flint was required to first signal the distinction. A true presystolic or auricular systolic murmur precedes the first sound sufficiently long to be recognized as such without difficulty. It is true that it is more liable to be counted diastolic than systolic.

And yet, now that the distinction has been pointed out, we conceive it would not be difficult for the trained and attentive ear to appreciate this initial systolic murmur as precedent to the first sound. The contrast in the note of the murmur and note of the sound would help the discrimination. And we know that reduplication of the cardiac sounds is well perceived, although here two similar notes must be as near, at least, as the dissimilar notes of the murmur and sound under consideration.

Then accepting the fact as set forth, that a cardiac murmur preceding the first sound may be audible in certain cases with healthy mitral but insufficient aortic valves, our explanation of the phenomenon is, that the murmur is systolic and produced at the aortic orifice, and begins before the culmination of the first sound because the blood is already flowing through the altered valves, throwing them into vibration, when the heart note is heard.

The discovery and appreciation of the phenomenon by our illustrious author was a very natural result in view of his large clinical experience, and exquisite aus-

cultatory powers, and the extreme care with which he investigates his cases. His interpretation was framed on the basis of the idea that the murmur was essentially mitral direct, and without reference to the positive results bearing upon the mechanism furnished by the graphic method. These results are too definite and significant to be neglected or ignored; and if we have succeeded in arriving at the true interpretation it is because we have studied the question in the light of the results of cardio-sphygmography.

As a term is needed to designate this murmur, let it be named the *Murmur of Flint*.

SOME OBSERVATIONS ON THE SALIVARY DIGESTION OF STARCH BY INFANTS.¹

BY J. M. KEATING, M. D.,

Visiting Obstetrician to the Philadelphia Hospital, and Lecturer on Diseases of Women and Children.

RECENTLY, in a late English work, I find the following: "During the first few months farinaceous food of every kind should be avoided, for the child's stomach (?) cannot digest it. Until the third month, or even later, no saliva is secreted, and without this floury foods cannot be assimilated."² This idea is so prevalent, and most of us have adopted the statement as representing the teaching of physiologists, that it has always been a matter of surprise to those interested in the feeding of infants to find occasionally, especially amongst the poorer classes, infants fed upon corn starch or other farina, almost to the exclusion of other food, and thrive.

At present we presume that amylaceous material has of necessity to be converted by hydration into glucose, and for this reason I will not detain you this evening by indulging in the more speculative aspect of this subject, as to whether dextrine is capable of being absorbed, and which of the two ferments, that of the salivary glands or of the pancreas, is of the most importance. We have left this matter for further investigation. Prof. Albert R. Leeds, in his very able *exposé* of the subject of foods as regards their chemical constituents, made the matter so clear that in his table of the analyses we have evidently an accurate guide for the selection of foods in individual cases. But as the general belief is that for infants of a tender age our choice should fall on that which contains a minimum quantity of starch, and a maximum amount of vegetable albuminoids, or foods based on the Liebig formula, I deemed it valuable to institute a series of experiments, the result of which I confess were rather surprising, to test the saliva of infants, and to satisfy myself that the reason why some children apparently thrive on starchy food is not due to any change in the starch in its preparation, but depended upon contact with secretions well established in childhood.

In these tests we endeavored, as far as possible, to exclude all error. Corn starch was used, it having been previously boiled, cooled into a paste, and portions of this was put into little linen bags, and given to infants to suck for two minutes at a time. Pavy's test was then used; the corn-starch paste exhibited before the experiment no evidence of sugar change.

To the resident physicians of the Philadelphia Hospital, Drs. B. F. Hawley and A. E. Roussel, I am indebted for assistance in this matter, as many of these tests were repeated a number of times by them, and great care was used to insure accuracy. My report includes the results obtained by experiments with the saliva of twenty-one children, varying in age from six days to seventeen months. The sugar change was noted in all but three,—one of these was a babe six days old,—whilst in another babe seven days old a marked reaction was observed. I feel satisfied that some infants do digest starch provided it is presented to them in a digestible form, and also that the salivary secretion, which occurs earlier than we have been accustomed to believe, is allowed to come in contact with it, and I cannot but attribute the many statements to the effect that starchy food in small quantities is contra-indicated to the fact that the secretions of the mouth are less liable to exert their influence when such food is administered by bottle and deposited in a surprisingly short time in the acid juices of the stomach. If starchy food, such as barley flour, oatmeal, rice, wheat flour, etc., is indicated on account of its highly nutritious qualities which exist in all portions of the grain and deemed advisable in the feeding of children, our few observations teach us that they should be administered in such a way as to insure their thorough digestion, and I am satisfied that the surprising results we witness, especially among the poor, of thriving table-fed babes, is due to the mode of feeding more than to the fact that they are exceptional and astonishing cases. My table shows that the age of the infant is not a guide to the quality of its saliva, and we should bear this in mind when choosing the form of food. Thus, should we be called upon to regulate an infant's feeding, it would be important for us to test the saliva.

If we find a sugar change taking place we might

incorporate with milk small quantities of one of the cereals, either barley, oatmeal, or wheat. On the contrary, should the test prove negative, Horlick's or Mellin's food would be decidedly preferable. But while thoroughly convinced that the saliva is a most important element in digestion we cannot overlook the fact that starchy foods have also to run the gauntlet of the pancreas, which organ, if it possess in childhood relatively the same power that it does in latter years, is far more active than the salivary glands. We cannot, then, overlook the value of a microscopic examination of the stools of all bottle-fed children, for I believe that by this alone we can regulate the quantity of farinaceous food, detecting the proportion of the undigested residue.

The following are my conclusions:—

The saliva of some infants possesses the property of converting starch into glucose, regardless of age.

The age of the infants cannot be taken as an indication of this property of its saliva.

When such a condition is found to exist a small quantity of well-prepared farinaceous food is valuable as an element in the diet, incorporated with mixed cow's milk.

An examination of the stools of children so fed would be a guide as to the quantity of starchy food to be used, and when farinaceous food is employed slow feeding is probably preferable to the bottle.

REPORT ON OBSTETRICS.

BY WILLIAM L. RICHARDSON, M. D.

PUERPERAL UTERINE ATROPHY.

DR. R. FROMMEL reports¹ twenty-eight cases of this rare result of the puerperal condition. The youngest case was nineteen years of age, and the oldest forty. Besides the uterine atrophy there was in most of the cases a general atrophy of the generative organs. According to the observations of Schröder there are three distinct varieties. One occurs early in the puerperal stage, and is especially liable to be found in patients suffering from tuberculosis, and also in those who have had puerperal septicæmia; another form occurs in women who are in a poorly nourished condition, although their labor and convalescence were normal; and still another variety is found in women who have well-marked puerperal disease. The symptoms which accompany this affection are amenorrhœa, fugitive pains, and many symptoms which would naturally be complained of by a patient suffering from hysteria. There is found on examination a state of vaginal subinvolution and a consequent tendency to prolapse. The uterine walls are thin; the uterus is generally atrophied, and there is less mobility. The disease is more frequently found in hospital than in private practice. Dr. Frommel found that the disease was most apt to come on in women who had become pregnant soon after marriage, had nursed their children, and had during the nursing become pregnant. He explains its occurrence by the fact that the generative organs seem to be exhausted, and, as a result, there is a long interval before the catamenia reappear, if at all. The prognosis in these cases is bad, and it frequently happens that the uterine and ovarian func-

¹ Zeitschrift f. Geb. v. Gyn., vii., 2.

tions are never restored. The treatment, of course, is tonic, and the adoption of measures to improve the general nutrition of the patient.

NITROUS OXIDE AS AN ANÆSTHETIC.

Dr. Tittel has administered nitrous oxide in fifty cases of labor. He finds¹ that under its influence the uterine contractions are increased in severity and become more frequent. The pulse of the mother is perceptibly lessened in frequency, while that of the child is decidedly increased. He thinks it of great advantage during the first stage in a primipara who is suffering severely, and also in cases of multiparæ when the pains occur at long intervals and are of slight severity. In four cases the patient was greatly relieved of a distressing nausea and vomiting. The nervous excitement, sometimes observed when nitrous oxide is used, was noticed in only two patients. One of these had a well marked hysterical attack, and the other epileptiform convulsions.

PUERPERAL DIABETES.

Dr. J. Matthews Duncan contributes a most valuable paper² on this very rare disease. In it he gives histories comprising twenty-two pregnancies in fifteen women, varying in age from twenty-one to thirty-eight years of age. So far as is known all, with one exception, were multiparæ. Of the twenty-two pregnancies in fifteen mothers four ended fatally after delivery. Hydramnios was frequent, and the liquor amnii in one case contained 0.7 per cent. of sugar, and in a second case there was also unquestionably sugar in the liquor amnii, although no quantitative examination was made. In seven of nineteen pregnancies, in fourteen mothers, the child died during the pregnancy, having in all of these reached a viable age. In two more the child was feeble, and died a few hours after birth. In one other case the child had diabetes. The dead fœtus was very large in many of the cases.

Dr. Duncan admits that the number of cases which he has been able to find is too small to possess any very great statistical value, but the histories seem to show—

- (1.) Diabetes may come on during pregnancy.
- (2.) Diabetes may occur only during pregnancy, being absent at other times.
- (3.) Diabetes may cease with the termination of pregnancy, recurring some time afterwards.
- (4.) Diabetes may come on soon after parturition.
- (5.) Diabetes may not return in a pregnancy occurring after its cure.
- (6.) Pregnancy may occur during diabetes.
- (7.) Pregnancy and parturition may be apparently unaffected in its healthy progress by diabetes.
- (8.) Pregnancy is very liable to be interrupted in its course, and probably always by the death of the fœtus.

PUERPERAL ECLAMPSIA.

Dr. Karl Breus reports³ six cases in which the patient was treated by diaphoresis. One patient, whose puerperal condition was complicated with cirrhosis of the liver, died, the other five recovered. The patient is placed in a bath at a temperature of 100.4° F., the head only being kept above the surface of the water.

¹ Wiener Med. Blätter, March 15, 1883.

² Transactions of the Obstetrical Society of London, vol. xxiv., p. 256.

³ Archiv für Gynäkologie, vol. xix., p. 11.

The temperature of the bath is then gradually raised as high as the patient can bear it. This is continued for about half an hour or until a profuse sweating appears on the head and face. The patient is then packed in a sheet, and covered with several blankets. The diaphoresis is continued for three or four hours. The patient meanwhile is encouraged to drink freely of soda water. Should eclamptic symptoms reappear the bath is again resorted to. At the same time an enemata of hydrate of chloral is given. In the first two cases Dr. Breus reported the convulsions occurred before delivery. In one case the attack came on at full term, and in the other at the sixth month. Soon after the bath was used the convulsions ceased, and both patients subsequently were delivered of living children. In the third case the convulsions occurred before the labor was completed, and continued after the delivery. In the fourth case the labor was nearly completed before the eclamptic seizure. Both of these patients made a good recovery, as did also the sixth, in whom the convulsions first occurred on the twenty-third day after delivery.

Reports of Societies.

PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

H. C. HAVEN, M. D., SECRETARY.

APRIL 28, 1883. Annual meeting. Dr. R. M. HODGES in the chair.

Dr. B. JOY JEFFRIES presented a communication entitled

THE QUICKEST, SUREST, AND MOST PRACTICAL METHOD OF ASCERTAINING DEFECTS IN THE CHROMATIC SENSE.

This, he said, was most undoubtedly Holmgren's with the worsteds, which, with its various imitations introduced by others, was exhibited and explained. It had become necessary to again call the attention of the profession to this method, since the papers have been constantly filled with false and silly statements about it, introduced by persons interested in attempting to prevent examinations for, and control of, defective vision on the railroads. So many members of the Society had, from conversation, also shown such a mistaken notion of the test that it must be again asserted that no names of colors are asked for by the examiner. The particular shade of green used for the first test corresponds to where in the spectrum the color-blind begin to lose the color and see only gray. The special value of the test was the very fact that the examined might be perfectly ignorant of color and color names, yet his chromatic sense could be determined by an expert with certainty and very quickly. Of course tests by railroad officials and employees, directed by the superintendents to examine and sign certificates, were worse than useless. They never have applied the test properly, and are wholly incapable of so doing. Thus ignorantly asking the names of the colors has given rise to the idea that it was a part of the test, and hence the sympathy excited for employees required "to be as versed as milliners," etc. Of course railroad officials and employees who desire to prevent examinations and the counsel they hire will persevere in their false statements as to the test which members of the

Society have seemingly come to believe as facts. Hence the need of explanation.

Dr. Jeffries also explained the absurdity of attempting to restrict, as was proposed in the legislative bill, the testing for color-blindness to the railroad signals, and showed that it was this year, as before, but a plausible attempt to do away with all examinations. The present law defines no method of testing, or any standard of requirement. The biennial examinations which were recommended to be and were dropped out had not been inserted by Dr. Jeffries, but by the railroad commissioners, who even advised annual ones in their report. The law as at present is hardly more than a recognition of the rights of the community, without any attempt at securing those rights. This can only be done by the legal enactment of standard methods and requirements, and the appointment of State experts thoroughly competent to decide *simply* whether an employee came up to such standard, and whose fee for the same is fixed, to be paid by the corporation, not the employee. The necessity for all this was very practically explained.

The speaker then showed how all officials had been deceived in attempting to test men declared defective. Whenever employees had been by *competent experts* declared color-blind, tests with flags and lanterns but confirmed this, when *properly and honestly carried out*.

Dr. Jeffries very specially dwelt upon the fact that learning to become an expert examiner was a matter of time, study, and practice, quoting the London Committee's report on this. Physicians could learn better than others. The surgeons of the marine hospital service had made few mistakes even at first in testing pilots.

As with the visual power so with the color sense, the amount to be required should vary with the position of the employee, hence the necessity of determining this with accuracy. The apparatus for doing this by experts was described, particularly Donder's and Holmgren's.

Dr. Jeffries related the cases of a number of the color-blind he had examined among railroad employees and pilots, and most practically showed how dangerous they were. Thanks were due to Holmgren for giving us a method so quickly carried out, so sure and so scientific that no excuse could be made for the employment of any one on land or sea whose chromatic defect endangered our lives or property. On the sea it was an international question, for the settlement of which a commission was necessary such as the speaker has been striving for some years to have established, and which must of course come in due time.

Dr. E. M. BUCKINGHAM asked if color-blindness was ever acquired in adult life.

Dr. JEFFRIES replied no, except as the result of some disease of the eye or brain, which in itself would most probably preclude the persons' employment on a railroad, and therefore he thought the requirements of biennial examinations superfluous as far as defective chromatic sense was concerned. But every employee who had been sick from fever, etc., or had been injured, should be retested as to color, and more especially as to his visual power. He cited several instances of employees who had been his patients, and whom no law prevented from returning to duty with most dangerous loss of eyesight, the road being protected by a certificate given by another

employee, perhaps years before, that his visual power was perfect.

Dr. C. H. WILLIAMS called attention to the instrument devised by Dr. Thomson, of Philadelphia, for the detection of color-blindness, which is in use on the Pennsylvania Railroad, and asked if any cases were known where this instrument had failed. With Thomson's test it seemed possible to have large numbers of men tested quickly by the officers of the road, for a record is made of each case by putting down the number of the skeins of worsted which were picked out to match the test colors; and the medical officer can detect at a glance on looking over those blanks the cases which are color-blind or which need further examination by an expert, for the real colors are marked with odd numbers and the confusion colors with even numbers, and the position of the skeins can be altered on the instrument so that fraud may be avoided. It seems much better to have an examination made in this way, subject to the supervision of experts, rather than not to have any examination whatever.

Dr. JEFFRIES replied that this method of Dr. Thomson, as he has frequently shown, deprived the examiner of watching the examined for the little arts which were so valuable as hints in diagnosis. The plan of the Pennsylvania Railroad Company was too costly to be carried out by our small roads. An expert could, as had the speaker, test in a car attached to the paymaster train the employees without taking them from their work. Their cases could be decided *then*, without loss of time or money to the company. The examiner should, of course, be legally appointed, and ascertain whether a man came up to equally legally established standards. As is done in Sweden under national laws, a sufficient number of experts can be appointed and taught by a competent head, who could retest when needed, precisely as Professor Holmgren is at the head of the control in Sweden. Holmgren's test is the quickest, and shows at once the defective. The case is settled then and there. Railroad officials may ask for further tests with flags and lanterns, to keep their peace with their men, but even these latter would soon get tired of such appeal. From such tests as are now made in Massachusetts, Dr. Jeffries would also appeal with the employees.

Dr. F. C. SHATTUCK read a paper entitled

THE DIAGNOSIS OF THE SO-CALLED "FUNCTIONAL MURMURS."¹

Dr. G. M. GARLAND presented a communication entitled

THEORIES REGARDING THE MECHANISM OF THE INORGANIC CARDIAC MURMURS.²

In the discussion which followed, Dr. J. J. PUTNAM stated that he believed he had recently seen an example of the functional diastolic murmurs of which Dr. Shattuck had spoken. It occurred in a very nervous and anæmic boy of twelve, with relapsing chorea, and had been present for several months.

The murmur was in character a soft but distinct whiff, and was heard along the left border of the sternum and nearly to the apex. It was thought at first to be organic, but the absence of signs of distinct enlargement, the presence of other (variable) murmurs which were evidently functional, the fact that

¹ Vide page 25 of this number of the JOURNAL.

² See page 28 of this number of the JOURNAL.

both sounds to the right of the sternum were clear, and that there was no regurgitant pulse in the retinal arteries, had led him to suspect that this also was functional. This suspicion had been strengthened by reading the cases of Weiss, to which Dr. Shattuck had referred him.

DR. HENRY I. BOWDITCH said that he was glad to note the conservative views of Dr. Shattuck in regard to condemning a patient because of a cardiac murmur. Dr. Bowditch thought physicians were rather apt to condemn patients, wherever there was a murmur, to a more or less invalid life forever afterwards, even though the patient may feel well, and the heart may be healthy in every other respect, and the cardiac functions properly performed. The shock of such a prognosis to the patient often becomes a very important element in the subsequent health, although the influence of that shock is often underrated by the attending physician; in truth it may be wholly ignored by him. Even in the most severe cases of organic cardiac disease we should always give a hopeful prognosis, and we never should declare the condition hopeless.

Dr. Bowditch instanced a case of most extreme severity, where orthopnoea had existed for three weeks, and there were all the undoubted signs of organic cardiac disease. The physician pronounced the case hopeless, yet she did recover so far as to be able to perform all the duties of an active life. She seemed comfortable and happy, and yet there were still present the signs of organic disease of the heart.

Dr. Bowditch gave the following formula, which he had often found of great service in relieving even the most serious cardiac affections:—

R Pulv. digitalis	gr. x.
Pulv. colchici semmi	gr. xx.
Sodæ bicarbonatis	gr. xxx.
In 20 pills or powder.	

One taken three or four times daily at first, and gradually lessened so that at last only one is taken at bedtime, and the treatment continued for three to nine months. It had been his invariable prescription for the last twenty-five years. It had been offered to him by the late Dr. Twitchell, of Keene, who had used it twenty-five years, and he himself had been advised to use it by the well-known Nathan Smith, of New Haven, who after an equally long experience had found it of great value. Dr. Bowditch had used, in addition, over the heart, for months, and as he believed with advantage, the following:—

R Iodinii	3 ss.
Ether	3 ss. M.

In confirmation of the assertion that there may exist for many years an evident valvular murmur unchangeable in character and without injury to health, Dr. Bowditch cited the fact that many years ago, when examining a patient, he had found a cardiac murmur, but as it apparently did not interfere with the health of the patient he had simply advised reduction of all action likely to stir up the heart. He had seen recently the same individual, and so far as he could judge from the old record, and that of to-day, the heart sound had not changed in the least, nor had the patient had any cardiac symptoms.

PLASTIC OPERATION FOR BURN.

DR. C. B. PORTER exhibited the result of a plastic operation for a burn of the fore-arm, received eighteen months previous, which had resulted in a cicatrix cov-

ering the anterior surface of the fore-arm and wrist, contracted so as to flex the hand on the fore-arm beyond a right angle. A flap was taken from the middle of the anterior surface of the abdomen, extending from the median line outwards and backwards to the lumbar region, where the pedicle was made. Relying on the lumbar branches of the abdominal aorta and the ileo-lumbar from the internal iliac to supply nourishment to the flap. The cicatrix was dissected off, laying bare the superficial group of muscles. The arm was fixed to the corresponding side, and the flap stitched into position. At the end of six weeks the pedicle was severed, the flap having firmly united. The result of the operation was a straight wrist, and a power of flexing the fingers, which was impossible before the operation, and the restoring to him a useful hand.

On recommendation of the Committee of Supervision, it was voted to omit all meetings of the general Society except the stated and annual meetings.

The officers were then elected for the ensuing year, the names of whom have been already published.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.¹

C. B. NANCYREDE, M. D., RECORDER.

DR. J. H. MUSSER for DR. R. M. GIRVIN reported a case of

CARCINOMA (SCIRRHUS) OF THE BREAST.

In November, 1882, Miss —, a lady of good circumstances, with a hereditary tendency to carcinoma and scrofulosis from the mother, noticed at the upper portion of her breast a small, extremely tender lump the size of a hickory nut. The nodule increased in size, and on the day of removal, February 17, 1883, was as large as a duck's egg in the first position mentioned. Neither at that time nor at any other time was the nipple either diseased or retracted, or the mamma discolored. The breast had never been injured. The lymphatics were not involved. The general health and nutrition were good.

The operation was performed on the above date by Dr. Girvin on account of severe paroxysmal pain. So severe was this symptom that a slight opium habit developed. The wound healed nicely. There has been no return of the disease (May 20th).

Examination of a section of the hard mass in the gland demonstrated it to be a scirrhous.

CARCINOMA (SCIRRHUS) OF THE RECTUM.

By J. H. MUSSER, M. D.

At the autopsy of the person from whom these specimens were removed, made thirty-six hours after death by Dr. W. E. Hughes, we found rigor mortis well marked, the body greatly emaciated, the skin of a yellow-earth color, and on the right buttock near the gluteal fold the ragged grayish openings of several sinuses, which, we subsequently proved, communicated with a sac behind the rectum. This sac opened into the rectum, which at that point was greatly dilated. At the bottom of the dilated pouch in the posterior wall, towards the anus and two and a half inches therefrom, was a hard mass. This mass was the size of a silver dollar, involved two thirds of the wall, but did not cause occlusion of the gut. The surface was ulcer-

¹ Concluded from page 15.

ated. The bowel towards the cæcum was dilated, the mucous membrane congested, and the muscular coat hypertrophied. The remainder of the intestine was normal, and the glands of the mesentery were only slightly enlarged. The liver weighed four and one half pounds, was very fatty, and in the left lobe a secondary mass larger than a walnut was found. The apex of the left lung was the seat of a small area of catarrhal pneumonia; the base was bound down by rather recent adhesions. Further than this, the tissues presented no other change than that due to wasting disease. Microscopical examination revealed the two nodules to be of the nature of a hard cancer.

The patient, a female, thirty-seven years old, had always been a dyspeptic and of a constipated habit. Her mother and one sister had died of cancer of the stomach, her maternal uncle of the same disease of the liver. I attended Mrs. R. from October 11, 1881, to February 7, 1882. She died in May of the latter year. From the 5th of August previous to my first visit she had been suffering from so-called dysentery, twenty to thirty bloody and mucous stools, with tormina and tenesmus. She had grown very feeble and lost much flesh. My notes state abdomen flat, tender all over, especially in the fossæ, but no tumor noticeable. Dysenteric diarrhœa continued, and I may say these discharges kept up during my attendance, at times better, again worse. The mucus was always present, the blood at times none, again slight, or again in large amounts. The appetite was poor, and her dyspepsia bad. The debility and emaciation progressed, and the appetite became less. In November I detected a hard tumor with apparently a raw surface, two inches and a half from the anus. Early in December she developed pneumonia, and on the 31st the acute pleurisy. During December and January she complained of pains in the legs and of severe cramps at night. In January she began to complain of pain in the right hip posteriorly. Local and internal remedies scarcely relieved it, and finally the post-rectal abscess discharge. Death from exhaustion ended the career of horrible suffering. I would remark that in all probability the obstinate constipation predisposed to the location of the disease. The constant irritation of the hardened fæces would tend to the deposition of the cancerous growth in this locality in a person predisposed to that disease. I have not seen constipation noted as a factor in the etiology of rectal carcinoma, but I think such a view plausible, and that we may infer the practical point, — the bowels to be kept free in the cancerously inclined.

SARCOMA OF THE BLADDER.

By J. H. MUSSER, M. D.

I am indebted to my friend, Dr. Samuel R. Skillern, for whom I made the autopsy, for the privilege of exhibiting this very interesting specimen. At the time of the examination the skin of the body was of the characteristic cachectic hue, the rigor mortis was marked, the emaciation considerable, though not striking, for on section there was a fair amount of fat in the abdominal walls and in the omentum, while the muscles were comparatively large. The abdominal cavity alone was examined. The peritonæum was healthy, the stomach and intestines of a normal appearance. Neither the mesenteric nor any other lymphatic glands were affected. The liver was slightly enlarged and fatty, the spleen normal. The genito-urinary tract was removed intact, the kidneys being severed from their

attachments with difficulty on account of being surrounded by fat. Beginning with the kidneys the left was about half the natural size, with thickened adherent capsule. The pelvis was very greatly dilated, the secreting portion reduced to one third the natural size. The medullary portion was mostly atrophied, the cortical was thin, hard, and pale. The right kidney was larger by one third than normal, was also cirrhotic, and although its pelvis was dilated the secreting portion was not atrophied very much. The ureters were very much dilated, averaging the size of the index finger. The bladder was in its normal position, and on opening, the calibre was found lessened by one half, the walls much hypertrophied. At the base of the bladder in the trigone vesicæ a flat tumor was detected. It measured two inches transversely, and one antero-posteriorly. The base of the tumor was smaller than the upper surface. This surface was irregular, at some places ulcerated, at others covered with phosphatic concretions. The orifices of the ureters were found by hydrostatic means to open into the tumor, and hence were somewhat occluded. The urethral canal was not encroached upon. To the left of the large tumor were two small secondary masses. Microscopical examination of the kidneys and the tumor: in the former interstitial and tubular nephritis was found. The tumor was of the histological appearance of a sarcoma. The sections are under the microscope for examination.

The person from whom these specimens were removed had been a successful minister in charge of a large congregation. He had always been a great mental worker. At the time of his death he was fifty years old. During his life his habits were most exemplary. His previous health was good. In his family history no evidence of hereditary disease could be traced. For the clinical history I am indebted to the various medical gentlemen that attended him.

Professor Agnew was consulted more than two years prior to death on account of vesical irritation. Six months thereafter he passed blood by the urethra. Careful examination at this time and before, both by the urethra and rectum, failed to detect any tumor or calculus. In a short time the cachectic hue became evident, and with all the professor suspected malignant disease. The hæmorrhages became more profuse and occurred more frequently. Professor Tyson was then consulted. He very kindly allows me to extract the following from his notes: —

Dr. Tyson said that Mr. S. first came under his observation May 27, 1880, being then forty-seven years old. He stated that he had been annoyed by frequent micturition for about five years, which gradually increased until at that time he had to rise two or three times each night, but thought it was more frequent during the day than at night. At first he was completely relieved of this symptom during his vacation, which he spent in the woods, and was still much better at such times. He thought Poland waters gave him relief, and he felt compelled to use it constantly. There was at this time a burning sensation at the neck of the bladder. The urine at this date contained one twelfth its bulk of albumen, enough blood corpuscles to give it a "smoke-hue," but no casts. On June 22d he again reported, Professor Agnew in the mean time having passed a sound, and detected a slight stricture, which he thought accounted for the symptoms. The patient was instructed to pass a sound for himself, and

he thought it gave him great relief, not only diminishing greatly the desire to pass water, but also relieving the sensation at the neck of the bladder.

Dr. Tyson did not see him again until October 31, 1881, when he reported that during the previous year he had been using the bougie at one time as often as five or six times a week, but more frequently every three or four days. He had been very well during this time, gaining ten pounds in his summer vacation, and at that time not urinating more frequently than any one else, although he kept up the use of Poland waters, of which he was drinking eight tumblers a day for five weeks while at the spring, and when at home five a day. He now mentioned that during the summer he felt an occasional soreness in the region of the bladder when stooping, and noticed also occasional chalky deposits in his urine. At the time of this visit his urine was acid, specific gravity 1014, and contained one fifth its bulk of albumen, but no tube casts. No note of blood was then made.

On November 7th his urine contained a sediment equal to about one tenth to one twelfth its bulk, which was composed mainly of blood corpuscles. There were a few leucocytes. He continued to visit Dr. Tyson until March 28, 1882. During much of this time he reported himself improved, there being much less frequent micturition at times, while the uncomfortable sensation at the neck of the bladder was less. The Poland water was discontinued, and ordinary drinking water substituted, with about the same effect in relieving the symptoms. During most of this time he took oil of eucalyptus in doses of from six to ten drops three times a day, we thought at the time with good effect, but the same changes occurred when he was taking nothing. His urine was always albuminous, sometimes containing blood appreciable to the naked eye. Once or twice he passed a small clot of blood from the bladder, and on January 7, 1882, a larger clot, which he compared to a small leech. Two or three times he brought chalky concretions, evidently phosphates, which he had passed. He always thought the bougie relieved him. He was always worse after a hard day's work, as on a Monday after preaching a couple of times Sunday. Benzoic acid and ergot were used with about the same effect. The oil of eucalyptus apparently gave temporary but no permanent advantage.

On March 28th he reported for the last time, and said that since his previous visit, seven weeks before, he had been very ill with what seemed to be an attack of great prostration, during which the urine was little altered except that there was increased phosphatic sediment. More recently, however, there seemed to be always, except for short intervals, more or less blood in the urine. At no time during his appearance did he present a cachectic appearance nor any other symptoms except those mentioned of intermittent hæmorrhage from the bladder and symptoms of vesical irritation, and malignant disease of the bladder had not been suspected while he was under his observation, but it was thought rather there might be a hæmorrhoidal condition of the prostatic plexus of vessels.

During the summer and fall of 1882 the general health of S. failed very much, while the vesical irritation was quite pronounced. When under Professor Agnew's care he began to use a sound, and at this time used it daily for its soothing effect. Along with the slight vesical tenesmus, he suffered from a little

pain at the head of the penis from the very first. During this time and in the winter the hæmorrhages continued. The blood was discharged before the urine; sometimes a considerable amount of pure blood, fluid, or in clots. The bloody discharges occurred with every urination, or days would pass by with clear discharges.

Dr. Skillern attended S. from 'January 9, 1883, until his death in March (13th). From his notes, in addition to the above, I glean the following facts: The occasion of the first visit to the patient was due to a fit which he had, and the nature of which was not clear, although it was probably a syncopal attack from blood loss. He suddenly became unconscious, and when seen had a pallid face, cold clammy extremities, a feeble pulse, and shallow respirations. There had been no convulsion, although slight convulsive movements were noticeable. Hypodermic injections of amyl nitrite soon aroused him, although he dozed for an hour afterwards. There is no evidence to prove that the seizure was uræmic. At this time his general condition was very bad. During January it is noted that he used the catheter frequently on account of a slight difficulty to start the flow of urine, and that in using it a grating sensation was felt by him; that the paroxysmal hæmorrhages continued; that the constant feeling of discomfort at the neck of the bladder and dysuria grew worse. Micturition occurred every two hours. In addition to the above in February he had morning nausea and vomiting, — generally losing his early meal, — becoming more frequent later in the month. The loss of flesh and strength became very evident, as did the cachectic appearance. Two weeks prior to death he began to complain of renal pain; the twenty-four hours prior the pain was agonizing. He died of exhaustion. It may be noted that the urine was never suppressed, nor was there ever marked vesical pain.

Dr. Formad expressed the opinion, from an examination of the urine several weeks before death, that malignant disease of the bladder was present, confirming the opinion of the other gentlemen. His opinion was based on the character of the epithelium in the deposit, being of the appearance of the deep layers of the bladder mucous membrane.

Dr. Agnew kindly informs me, without referring to his notes, that he distinctly recalls four cases of sarcoma of the bladder, all in males; and in all bloody urine was an early and constantly recurring symptom, amounting in one of the cases to very profuse hæmorrhages. Pain in one or both hips was also an early symptom. The patients were all over forty years of age.

This interesting note calls attention to the chief facts of these cases, and an especially noteworthy one, — the age of the patient. As is well known, sarcoma in other situations generally occurs in early life; this in later life. Then an examination of the relation of the mouth of the urethra to the flat tumor will show how readily a sound could have passed over the tumor, while the base of the bladder being filled the sound could not engage the mass. The enlarged prostate was no doubt deceptive, obscuring the basal mass when rectal touch was made.

— Dr. Louvain, of Carlsbad, has met with several cases in which difficulty of breathing was due to the administration of moderate doses of salicylic acid; the breathing was labored and rapid.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.

W. H. TAYLOR, RECORDING SECRETARY.

THE sixth annual meeting was called to order at the rooms of the Boston Medical Library Association, on June 12, 1883, at 11.15 A. M., by PRESIDENT PRESBREY. Twenty-one members were present. Records of the last meeting were read and approved.

The report of the Executive Board, showing the work of the medical examiners throughout the State who are members of this Society, was read by Corresponding Secretary PINKHAM, and accepted.

Medical Examiner PINKHAM, in his report, referred to the large amount of work involved in using the present form of blank for report of cases, and made some suggestions for a blank form which would in a great measure obviate this labor.

Voted, on motion of Medical Examiner Hurd, that the Executive Board be authorized to prepare blanks as proposed by the corresponding secretary.

Voted, on motion of Medical Examiner Tower, that the corresponding secretary be instructed to request members to report cases of special interest for publication.

Upon recommendation of the Executive Board Medical Examiner F. K. Paddock, of Pittsfield, was unanimously elected a member of the Society.

The treasurer made his report, which was accepted.

Voted, on motion of Medical Examiner Pinkham, that a committee of three be appointed by the chair to retire and report a list of nominations for officers for the ensuing year.

The President appointed Medical Examiners Harris, Hurd, and Pinkham as such committee.

The committee having retired reported the following list, which was unanimously adopted: For President, Medical Examiner S. D. Presbrey, of Taunton; Vice-President, Medical Examiner F. Winsor, of Winchester; Corresponding Secretary, Medical Examiner J. G. Pinkham, of Lynn; Recording Secretary, Medical Examiner W. H. Taylor, of New Bedford; Treasurer, Medical Examiner C. C. Tower, of South Weymouth.

The President appointed as Executive Committee Medical Examiners F. W. Draper, of Boston; Y. G. Hurd, of Ipswich; and J. C. Gleason, of Rockland.

Medical Examiner O. T. HOWE, of Lawrence, read a paper entitled *A Strange Case*, being the report of a suicide attended with unusual circumstances. The paper was listened to with much interest, and was received with applause by the Society.

Medical Examiner J. G. PINKHAM, of Lynn, read a paper on Infanticide, with Report of a Case of Infanticide by Drowning. The speaker's remarks commanded the close attention of the members, and were received with applause.

Both papers were the subjects of interesting discussions.

It was voted to dispose of the copies of the Transactions now on hand and to be published, to members and ex-members of this Society at the discretion of, and upon application to, the treasurer.

—Tending to corroborate the idea that malaria is caused by any vegetable decomposition is the case reported by Dr. Eichwald, of St. Petersburg, of a lady who lived constantly in a room filled with flowers in pots, and who thus acquired an intermittent fever with symptoms of true malaria.

Recent Literature.

Therapeutic Hand-Book of the United States Pharmacopœia, being a Condensed Statement of the Physiological and Toxic Action, Medicinal Value, Methods of Administration, and Doses of the Drugs and Preparations of the Pharmacopœia for 1880. By ROBERT T. EDES, A. B., M. D. (Harvard), Professor of Materia Medica in Harvard University, etc., etc. 397 pages. New York: William Wood & Co.

Our present official list is so good that physicians ought to become more familiar with it, and any work which will help to do this should be welcomed. The hand-book which we are considering is eminently fitted to accomplish this and more.

The arrangement of this excellent work is an alphabetical one like that of the Pharmacopœia. The directions for making the preparations are replaced by an outline of their physiological, chemical, and especially their therapeutic and toxic properties. This has been done with great care, and the author has succeeded admirably in giving in a clear and concise manner what is most essential. In addition to official title the common name, the French, German, and that by which many of the drugs are known in foreign pharmacopœias are given. To each of the more important drugs a few pages are devoted, many are mentioned only briefly, and under some headings the dose only is given. The increased strength of the opium preparations is carefully noted. A pharmacopœia almost necessarily includes a very large number of things which are of slight importance. In a new edition of the therapeutic hand-book many of these might be omitted from the text at least, they being retained, perhaps, in the index, and distinguished from the others by different type. It would be useful to know the proportion of the ingredients in certain of the preparations, for example, that liquor pepsini contains saccharated pepsin, 4, dilute muriatic acid, 1.2, glycerine, 40, water ad., 100; or that the syrup of the hypophosphites with iron contains one per cent. of lactate of iron.

The author says he "has endeavored to suggest, so far as possible, principles of treatment rather than to mention the name of each disease in which each drug has been or may be used." This choice deserves warm commendation.

Two tables such as are in the Pharmacopœia, one of solubilities, and the other a table including the more important changes in the strength of preparations in the last and present Pharmacopœias, might be found useful.

The book is one which should be studied by every practitioner and student of medicine.

The Practitioner's Ready Reference Book. A Handy Guide in Office and Bedside Practice. By RICHARD J. DUNGLISON, A. M., M. D. Third edition, thoroughly revised and enlarged. Philadelphia: P. Blakiston, Son & Co. 1883.

This third edition of this useful book has been not only revised, but very considerably enlarged with much matter, a ready access to which is of moment to the practitioner. The book is valuable for its purpose, and thorough, and has attained an assured popularity. We regret to see the offensive word *allopath* used in any connection on its pages.

Medical and Surgical Journal.

THURSDAY, JULY 12, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE MEDICAL ASPECTS OF THE TIME OF THE STUARTS.

THE JOURNAL in a previous issue has alluded to a few items of medical interest in the England of two centuries ago. We have thought that our readers might enjoy some further glimpses of the same period. We are indebted for the facts, as before, to the paper of Dr. Macdonnell read before the Athenæum Club, and published in the May and June numbers of the *Canada Medical and Surgical Journal*.

Political considerations, of course, influenced, in a measure, the *personnel* of the court physicians, though the favorite attendant of Cromwell, who, at least in his younger days, was a great hypochondriac, was a royalist. On the other hand the attendants who were allowed the executed monarch were roundheads. We are told that one Trapham, surgeon-in-chief to the army of Oliver Cromwell, embalmed the king's body, and that during the operation he uttered several coarse jests and unfeeling expressions. Yet, though he did say that he was stitching on the head of a goose, he did his work well. After 165 years the features of the king were plainly recognizable, bearing a striking resemblance to his portrait in coins, busts, and paintings. The fourth cervical vertebra was found smoothly divided transversely.

Some interesting contemporary opinions are given by Dr. Macdonnell regarding Harvey, who, by the way, it appears died in affluence and esteem instead of the poverty and neglect which some have ascribed to him. His good fortune was due, in part, to the fact that the royal whim took a fancy to physiological investigations, and made them popular. Harvey's experiments greatly interested Charles I., and the fashionables of 1642, instead of, as in 1882, throwing obstacles in the way of advancing science, not only witnessed dissections of living animals, but actually furnished the subjects for them. Aiken tells us that the interest his majesty took in Harvey's researches were of singular service to him in his investigations concerning the nature of generation, as the king's favorite diversion of stag-hunting furnished him with an opportunity of dissecting a vast number of animals of that species in a pregnant state.

Cromwell's death was apparently due to fever and ague, to which James I. also fell a victim. The Great Protector, who was probably predisposed to his fatal illness by the depression due to family griefs (notably the death of his daughter by cancer) as well as by an intercurrent attack of gout, had a persistent belief

that he would recover, and his physicians (with the apparent exception of the royalist above mentioned) betook themselves with great fervor to prayer, the patient saying, "Ye may have skill in the nature of things, yet nature can do more than all physicians together, and God is far above nature." Cromwell was the last Englishman of note to die of ague, cinchona bark coming into use in England about 1655. Unfortunately its use received a check at the beginning on account of the death of an alderman while he was taking the bark. This gave rise to so much public talk of its dangers that physicians feared to use it. The malarious character of the English climate at that period is thus explained: The soil about London was neither drained nor, during some months of the year, cultivated. The marshes of Cambridgeshire and Lincolnshire were covered with clouds of cranes. Southwark was a swamp, and at Westminster there is a gate called the Marshgate, from being situated in a place where there was once a marsh. Ague was less prevalent after the Great Fire. The number of deaths decreased per annum rapidly. In 1728 there were forty-four, and in 1730 only sixteen. In the ten years from 1800 to 1810 four deaths were registered. Dr. Caius says that ague was so fatal in London in 1558 that the living could hardly bury the dead. Burnet says it raged like a plague. According to Sydenham, from 1561 to 1565 it was the most fatal disease in England. In the Walcheren expedition 10,000 men, two thirds of the English force, died of marsh fever.

The body of Cromwell was got rid of in some mysterious manner immediately after the autopsy was over. A wax figure in a suit of velvet, richly laced with gold and trimmed in ermine, lay in state in Somerset House, in a room hung with black velvet, until 23d November, when it was buried in the abbey. The ceremony cost £6000. The "mummery" of a funeral service over a coffin containing no corpse is not, as we thus see, entirely a peculiarity of almshouse management, nor, as has recently been intimated in certain quarters in this State, is it a trick practiced only on those who are too poor to prevent it. In 1660 the Lords and Commons thought that they might then with safety kick the dead lion. An order was passed "that the carcasses of Oliver Cromwell, Henry Ireton, John Bradshaw, and Thomas Pride, whether buried in Westminster Abbey or elsewhere, be with all expedition taken up and drawn upon a hurdle to Tyburne, and there hanged up in their coffins for some time, and after that buried under the said gallows." In a pamphlet in the Harleian Miscellany it is recorded that a certain clergyman, whose name is not given, made a sworn statement shortly after this desecration of Cromwell's remains that roundheads in disguise had taken that of Charles I. from its resting-place, and substituted it for that of Cromwell. Although a dead body of an unknown person took the place yet it was highly improbable that it was that of the king, for, as has been mentioned, the royal corpse was found intact in the beginning of this century in its coffin. At all events

the body of Cromwell was never found, and it is supposed that his friends, anticipating that it would some time be molested, procured medical "opinion" that a likelihood of unusually rapid decomposition necessitated its early interment. Thus it was quickly and quietly disposed of.

At the restoration Charles II. did not remove the former court physicians, but added a number whose morality was congenial with his own. Like his father, this king also dabbled in anatomy, and Pepys says that in 1663 he witnessed the dissection of three human bodies by Dr. Clarke and Mr. Pierce the surgeons, with which he was "highly pleased."

Of the medical friends of Charles II., Hamey was apparently the most respectable. A Fellow of the R. C. P. in 1634, he commenced the uphill drudgery of practice with the mill-stone of poverty about his neck. He was a faithful churchman, and a devoted royalist. The downfall of Charles I. caused a great falling off in his practice; indeed to such want was he reduced that he was on the point of quitting London, when a fortunate event occurred which not only relieved present necessities, but which put him at once into affluent circumstances, enabling him to send Charles II. sums of money he had obtained by the spoiling of the Egyptians. Mr. Palmer, a kinsman, in his biography of Dr. Hamey, tells the story:—

"Things had been going the wrong way with Hamey for some time. Most of his cavalier patients were in exile, and those at home had no fees to give him. Anxiety had brought on illness which prevented him entirely from earning his daily bread. There was not a penny in the house. The very first time he dined in his parlor afterwards a certain great man in high station came to consult him '*ratione vagi sui amoris*,' says Dr. Hamey, and 'he was one of the godly ones, too, of those times.' In fact it was no other than the pious Ireton.

"After the doctor had received him in his study, and modestly attended to his long religious preface, with which he introduced his ignominious circumstances, and Dr. Hamey had assured him of his fidelity, and given him hopes of success in his affair, the generous soldier drew out of his pocket a bag of gold, and offered it all in a lump to his physician. Dr. Hamey, surprised at so extraordinary a fee, modestly declined the acceptance of it, upon which the great man dipping his hand into the bag grasped up as much of his coin as his fist could hold and generously put it into the doctor's pocket, and so took his leave." This successful case brought the physician others of a similar nature from patients of the same class, so that it marked the beginning of his fortune.

The rest of Charles's special physicians were a bad lot. One named Archer especially encouraged the king in the pursuit of his sensual pleasures. His essay on the advantages to be derived from intemperate drinking was entitled, *The Possibility of Maintaining Life from Infancy to Old Age without Sickness by the Use of Wine*. Pepys seems to have been quite fascinated by some of the doctors' stories. He quotes one where the college, apparently for the sake of a "lark," in-

duced a poverty-stricken old debauchée, for the sum of twenty shillings, to allow twelve ounces of sheep's blood to be injected into his vein. The jokers seem to have been disappointed at the harmless result of their experiment. Pepys concludes a description of these gentlemen's pleasant stories as follows:—

"On this occasion Dr. Whistler told a pretty story related by Muffett, a good author, of Dr. Caius, that built Caius College; that being very old, and living only at that time upon woman's milk, he while he fed upon the milk of an angry, fretful woman became so himself; and then being advised to take it of a good-natured, patient woman he did become so beyond the common temper of his age. Their discourse was very fine; and if I should be put out of my office I do take great content in the liberty I shall be at of frequenting these gentlemen's company."

The last illness of Charles II. (who died of apoplexy after four days' sickness) is thus described:—

"At eight A. M. the king lost speech and motion. He was engaged at the time in making chemical experiments. Sir Edmund King, surgeon employed in the army, who was giving the king instructions in the laboratory, ran to his assistance and promptly bled him to the extent of sixteen ounces. King, for his presence of mind, was awarded a vote of thanks from Parliament, and a gift of £1000. He got the thanks, but never the money. The court physicians to the number of fourteen then arrived. They approved of what had been done, and ordered further venesection to the extent of eight additional ounces. An antimonial emetic, a powerful purgative, and several clysters were administered. A blister to the head was applied. The king did not rally, but remained until death in a lethargic, dreamy condition. The loss of the power of coördinating words added to the misery of his condition. Conflicting ecclesiastics struggled for an audience at each glimmer of consciousness. He probably said 'yes, yes,' or 'no, no,' to all interrogations indifferently, agreeing with the last speaker, not knowing the meaning of the words he uttered."

Macaulay's version of the story of the king's death can scarcely be correct. It is unlikely that a person in the king's state, with the brain compressed as it was found to be, would be sitting up in bed, exchanging polite speeches with the courtiers, and apologizing for the unconscionable time he took in dying.

MEDICAL DIPLOMAS IN MASSACHUSETTS.

It is with much satisfaction that we refer again to the matter of bogus diplomas. The anomalous condition of affairs which has existed in this State has been decidedly improved by the following act, which received the sanction of the executive on June 30th:—

An act to prohibit certain medical societies from conferring degrees.

Be it enacted by the Senate and House of Representatives in general court assembled, and by the authority of the same, as follows:—

SECTION 1. No corporation organized for medical purposes

under the provisions of Chapter 115 of the Public Statutes shall confer degrees or issue diplomas or certificates conferring or purporting to confer degrees unless specially authorized by the Legislature so to do.

SECT. 2. An officer, agent, or servant of any corporation mentioned in Section 1, or any other person conferring degrees, or signing, issuing, or authorizing the signing or issuing of any diploma or certificate purporting to confer any degree of medicine or surgery, contrary to the provisions of this act, shall be punished by fine of not less than \$500, nor more than \$1000.

It will be remembered that the officials of the Bellevue School were discharged from custody on an opinion that the sale of diplomas by corporations incorporated under the general laws of the State was not forbidden by law. The Legislature has wisely filled the gap.

ESERINE IN DIARRHŒA.

DR. ESCHLE, in the *Neurologisches Centralblatt*, May 15th, reports observations made in the Richter'schen Heilanstalt (Pankow-Berlin) on the curative effects of calabar bean preparations in catarrhal conditions of the digestive tract. Eserine (physostigmin), the alkaloid which with calabarin is found in the seed of the physostigma venenosum, was used some time ago in the same institution, where it gave great satisfaction in quieting maniacal patients, and for such paralytics as were not liable to apoplectic attacks. The action of the drug proved similar to, though more lasting and reliable than that of, hyoscyamin. The method of exhibition was by the subcutaneous injection of a one half per cent. solution of sulphate of eserine in doses of .001 gramme to .0015 gramme. Its use was found to be always attended by alteration in the digestive organs. One maniacal patient who cried out continuously was quieted by the use of .0025 gramme; this rather large injection caused vomiting and free watery stools. The use of smaller doses quieted the psychical and motor restlessness, and produced sleep without vomiting or defecation. In three other patients (paralytics) stoppage was noted for over thirty-six hours, vomiting occurring only once. Quiet in bed was always ordered. The special object of the communication was to report the results of the use of eserine in three cases of intestinal catarrh.

The first patient suffered from an attack of this nature, causing continual desire to defecate, with a passage every half hour during the second day. Hypodermic injection on this day of .001 gramme of the eserine solution produced sleep in an hour and a half, which lasted from two o'clock till evening. No passage occurred until forty-six hours after the injection.

In the second case intestinal catarrh was brought on by a cold. A large number of watery stools were passed during the night and on the following morning. The same dose was administered at 10.30 A. M. The patient complained of general weakness and of numbness in the arm in which the injection was made. The pulse was slowed, but remained moderately strong. At four P. M. a watery passage occurred, after which none until twenty-seven hours after the injection, followed by stoppage of thirty-six hours; there was no vomiting. The patient was quite comfortable on the

evening of the day of the injection, having passed the afternoon half asleep.

The third patient, a man of thirty-nine years, suffered from chronic dysentery, acquired in Africa. On the day before the medicine was used twenty-four bloody stools were counted by the attendants. On the day of the first injection (.001 eserine sulph.) twelve stools were passed of unchanged character. During the twenty-four hours following the second injection (.0015) there were five passages striped with blood, and during the next twenty-four hours, four bloody stools. In the two days following the third injection (.0015) seven stools were passed, of which three were accompanied by blood. During the four days following the fourth injection (.0015) the passages varied from one to six, some with and some without blood. Vomiting followed the first two injections only. The writer remarks that although the last case was not watched to its termination, and although he could not promise himself a perfect cure, the result was sufficiently marked to illustrate the beneficial action of the drug in this dose in limiting the weakening hæmorrhages and albuminous stools. He also announces his intention of instituting shortly experiments on animals with regard to the contradictory action of the drug in large and small doses, a peculiarity already noticed in other medicaments.

MEDICAL NOTES.

— In an interesting letter to the *Boston Herald* a recent correspondent, in speaking of steamer life, criticises very justly the custom of loading down parting friends with flowers, whose odors after a few days add to the discomforts of the journey, while sentimentality prevents their being thrown overboard. This writer suggests that it would be wiser to substitute fruit, which is sure to be appreciated without adding to the disagreeable elements of sea-sickness. Practical as this suggestion is, the views of this malady expressed in the letter are certainly founded on fair-weather experiences. Arguing from the fact that the best medical authorities consider the malady cerebral, the conclusion is drawn that an exertion of the will, seconded by small doses of bromide of sodium, will overcome the difficulty. Even the late Dr. Beard, enthusiast as he was on the subject of the bromide, allowed that it was useless in small doses, and as for the other remedy suggested, we fear that the effort of will required to hold the symptoms in check during a severe blow would rack the strongest constitution.

— C. Ashton has studied the action of the heart in hibernating helices. The observation is difficult owing to the opacity of the parts and the necessity of guarding against the temperature radiating from the observer's body. The pulse seems to be irregular, or rather, perhaps, to pass through active and quiescent cycles. Absolute inactivity of the heart probably does not occur during hibernation. Under scrutiny the pulsations varied from three to twenty-two per minute. The animal is extremely susceptible to changes of temperature, as a touch of the finger will often

double the rate of pulsation, which also rises with exercise or motion. — *Quarterly Journal*.

NEW YORK.

— The deaths in the city for the six months ending June 30th numbered 17,174, against 19,906 for the first six months of 1882. Of the deaths from contagious diseases, 12 were from small-pox, 494 from measles, 549 from scarlet fever, 537 from diphtheria, 168 from whooping-cough, 6 from typhus fever, 118 from typhoid fever, and 130 from cerebro-spinal meningitis. Of the other deaths, 626 were from diarrhoeal diseases, 2795 from phthisis, 2291 from pneumonia, 877 from bronchitis, 917 from Bright's disease, 330 from croup, and 918 from disease of the heart. Of the total number of deaths 6558 were of children under five years of age, being 2505 less of this class than occurred during the first six months of 1882. During the six months 13,987 births were reported; an increase of 859 over the corresponding period of last year.

— The work of the summer auxiliary corps of physicians acting as sanitary inspectors, will, no doubt, prove more satisfactory this year than during any previous season from the fact that the appropriation for the present summer is sufficient to allow of the work being carried on for a much longer period than usual. Hitherto this special tenement-house service covered only five weeks, for which each of the fifty physicians of the corps received one hundred dollars; but this year it will embrace the entire months of July and August, and each physician will receive two hundred dollars for his services. Of the 78,368 houses used for dwelling purposes in the city, 35,000 are tenements, and 18,966 contain more than one family on a floor. During the five weeks of the service last summer the inspectors visited 153,982 families, and wrote 3671 prescriptions.

— The State Board of Health met at Albany June 29th, when the sanitary committee presented a detailed statement of its work under the laws in preventing the adulteration of food and drugs, and the sale and use of dangerous illuminating fluids. During the meeting Commissioner Erastus Brooks called attention to the alarming increase of pleuro-pneumonia among milch cows on Staten Island, and the Board passed a resolution asking the National Commission on Cattle Plagues to take action in the matter. In the meanwhile the local boards of health on the island are doing all in their power to prevent the further progress of the disease. As soon as an animal is attacked it is killed and buried, and the rest of the herd placed in quarantine. In two cases the carcasses of diseased animals, which had been sold to the butcher as soon as the sickness was noticed, were found in the meat markets about to be offered for sale.

PHILADELPHIA.

— The resignation of Professor Wallace from the chair of Obstetrics and Diseases of Women in the Jefferson Medical College, which took every one by surprise last month, has been followed by the election

of Prof. T. Parvin, of Indianapolis, to the vacant chair on the 24th ult., an action on the part of the trustees which was also a surprise to many, and a very agreeable one to most of those who have learned of it. Professor Parvin returns to this city after several years' absence, ripe in years, honors, and experience. He is so well and favorably known as a teacher and practitioner, as an editor and operator, that he needs no introduction to the American medical profession; there can be no question but that the Faculty of Jefferson College has been strengthened by this latest addition.

— The Polyclinic, whose success has been quite satisfactory, has now to compete with another rival, a recently created Post-Graduate Faculty at Jefferson College. There should be abundance of occupation for several schools of this kind in Philadelphia; if the attainments of the average student upon graduation may be taken as any indication, the polyclinics should be no less numerous than the medical colleges themselves. A professor of the University of Pennsylvania, indeed, very aptly compared the medical neonatus to the young marsupial, and said that he should not venture far from his mother's pouch nor attempt to go alone for some time after his birth.

CHICAGO.

— For ten years Illinois has had a liberal law regarding material for dissections. For several years the unclaimed bodies of known paupers dying in the hospital for such cases have been given to the colleges for dissection in accordance with the clear provisions of the law. But the law says such bodies *may* — not *shall* — be turned over to the colleges, so now the Board of County Commissioners have voted that no more bodies shall be given to the colleges, but that all shall be buried at the county expense, and they have bought horses and wagons and hired men to do this work. All this because the last county undertaker was guilty of illegal practices. It is alleged that he sold bodies out of the State, which is contrary to the law. There is not the smallest claim that the colleges have abused their privileges under the law. Yet this action is taken by the commissioners, a clear invitation to the colleges (if it means anything) to get their material by the methods in vogue before the law was passed.

— The building for the hospital of Rush Medical College will be commenced in a few days. It is to be located on a lot adjoining that on which the college stands, and immediately north of it. The structure will be about forty-five by seventy-eight feet on the ground, and will have four stories above a high basement. Friends of the college say it will be ready for occupancy by New Year's day. It is the intention of the college to add to the hospital building eventually, so that when finished it shall be at least three times as large as the building now in course of erection. Sufficient land has already been secured to enable extensive additions to be made.

This will be the only hospital in the West Division of the city, except the County Hospital, for the care

of general hospital cases. The only other hospital in this division of the city, which, by the way, has as much territory and as many people as all the rest of the city together, is the little "Hospital for Women and Children," which has a capacity of not more than twenty-five beds.

Correspondence.

LETTER FROM MAINE.

MR. EDITOR, — After the lapse of more than a year since the resignation of Dr. Harlow, the Maine Insane Hospital at Augusta has a new superintendent. Though candidates were abundant, the Trustees were unable to agree upon one, and finally requested Dr. B. T. Sanborn, who for sixteen years has been first assistant physician, to apply for the place. The methods pursued in the management of the institution will doubtless be identical with those which have characterized it for forty years past.

An attempt was made last year to induce the Trustees to elect a woman physician to have medical charge of the female inmates; but, as this failed, the present Legislature was petitioned to take action in the matter. The numerous memorials were referred to the Committee on the Hospital, and a public hearing was given at which most of the Trustees were present, one of them being in favor, one neutral, and, apparently, all the rest opposed to the measure. The committee decided that the Trustees should settle the affair, which was a very effectual method of killing the project, considering the pronounced hostility of a majority of the board. The principal point of strictly medical interest in the case is with reference to the amount of disease of the generative organs said to exist among the female inmates. The exact or even approximate figures were not given; but opponents of the proposed introduction of a woman as assistant physician asserted that the amount of such disease requiring treatment was extremely small. An eminent alienist has recently reported that he has found eighty per cent. of his female patients afflicted with disease of the sexual apparatus. It would be interesting to learn why the crazy women of this State are so wonderfully exempt from maladies requiring the skill of the gynecologist, for it is certain that their sound-minded sisters are not similarly blessed. Indeed, it would almost seem that the possession of uterine or ovarian disease in this region is incompatible with lunacy.

A subject which attracted a good deal of attention in the profession was the attempt to procure a law for the registration of practitioners of medicine. The measure was presented by Dr. O. A. Horr, of Lewiston, who was a member of the House of Representatives. The bill provided that graduates of any institution legally qualified to confer medical degrees, and all who had practiced without a diploma for thirteen or more years continuously, should be allowed to register; and that all persons practicing medicine without having been registered should be deemed guilty of a misdemeanor, and on conviction thereof be punished for every offence by a fine of from one hundred to five hundred dollars, or by imprisonment for a term of from three months to a year, or both. It will be seen at a glance that this was not a strong bill, for it admitted to registration the very worst of the quacks; but it

was believed to be impossible to get a law which should require every physician to be the possessor of a diploma from a respectable medical school, and it was thought best to try to get one which would be advantageous in the future, even if something was sacrificed in the present. The ignorant pretenders would die out after awhile, and in a dozen years or so there would be a great improvement in the quality of practitioners. The homœopaths quite generally favored the bill; but the eclectics, botanics, magnetics, Druids, and the like joined forces against it, and it was defeated by a small majority. As usual, the physicians who urged the passage of the bill got only abuse for their attempts to protect the public against the homicidal incompetence of the quacks; and some of us were led to query if it would not be better to wait until the people themselves ask for some law to shield them from the charlatans. But this feeling of discouragement and disgust will wear away in time; and when the next Legislature convenes it is quite probable that the same men will be seen again in the capitol working for the interests of an unappreciative public, whose injuries at the hands of quacks have aroused anew in the educated physicians a sympathy and indignation which displace all indifference to the general welfare. By the way, I wonder if you have in Massachusetts any of that class of doctors called Druids. It is said there are many in Maine; and they have in Lewiston a college which is chartered under the simple and unostentatious name of *The Penobscot Valley Gorsedh of Bards and State of Maine Branch of the Druidic University of America*. I may have something to say about this in a subsequent letter.

The Medical School of Maine, at Brunswick, has just completed a very prosperous term. Prof. Charles O. Hunt gave the opening lecture, discussing the germ theory of disease very interestingly and ably. The address at the close of the term was given by the Hon. Charles F. Libby, recently mayor of Portland, and a prominent member of the Cumberland bar. His subject was Professional Study and Work, and it was developed in a most scholarly and graceful manner. Twenty per cent. of the students in the school had college degrees. Twenty-eight candidates were graduated.

The Portland School for Medical Instruction opens this summer with the largest class which has ever attended.

The thirty-first annual meeting of the Maine Medical Association was held in Portland on the 12th, 13th, and 14th of June. The President, Dr. George E. Brickett, of Augusta, occupied the chair. The finances of the Society are in an excellent condition, thanks to the efficiency and fidelity of the Treasurer, Dr. A. S. Thayer, of Portland, to whom the Association presented its thanks and voted a salary of twenty-five dollars a year.

The amendments to the Constitution, proposed by Dr. E. F. Sanger, of Bangor, received no affirmative votes, and consequently failed of adoption.

The oration was given by Dr. M. C. Wedgwood, of Lewiston, who discoursed entertainingly on Rational Medicine and Quackery. He did not, as is so customary with writers of medical addresses, take the beaten track of denunciation of one or two prominent sects of practitioners; but, what was much more judicious and profitable, he pointed out and held up to merited contempt the charlatany of many men in our own ranks. Verily, the most irritating displays of quackery are

those made by regular physicians, on whom no written code can lay a finger or apply the toe of its boot.

Papers were read on Synovitis, by Dr. J. G. Pierce, of Freeport; on Acute Inflammation of the Middle Ear, by Dr. A. K. P. Meserve, of Portland; on Extra-Uterine Pregnancy, by Dr. H. N. Small, of Portland; on Fractures of the Elbow-Joint, by Dr. S. H. Weeks, of Portland; on Disease of the Mastoid, by Dr. E. E. Holt, of Portland; on the Induction of Premature Labor, by Dr. A. H. Burbank, of Yarmouth; on Bright's Disease, by Dr. I. T. Dana, of Portland; and on the Treatment of Accidents occurring during Parturition, by Dr. S. C. Gordon, of Portland. Dr. S. P. Warren, of Portland, reported a case of Absence of the Uterus, and one of Cyst of the Vesico-Vaginal Wall; Dr. J. A. Spalding, of Portland, a case of Injury to the Eye; Dr. B. F. Sturgis, of Auburn, a case of Chronic Abscess of the Tibia; Dr. F. H. Gerrish, of Portland, a case of Septum of the Bladder, preventing Lithotrity; and Dr. Weeks, of Portland, a case of Sarcoma of the Scalp. Cases were also reported by several of the readers of papers, and by others in the discussions, some of which were quite animated.

The following officers were elected for the ensuing year: President, Dr. O. A. Horr, of Lewiston; Vice-Presidents, Drs. L. W. Pendleton, of Portland, and D. E. Marston, of Monmouth; Corresponding Secretary, Dr. J. O. Webster, of Augusta; Board of Censors, Drs. H. N. Small, of Portland, W. K. Oakes, of Auburn, J. M. Bates, of Yarmouth, W. B. Cobb, of Standish, and J. D. Nutting, of Hallowell; Committee on Publication, Drs. C. D. Smith, C. O. Hunt, and G. H. Cummings, of Portland, C. A. Packard, of Bath, and B. F. Sturgis, of Auburn; Business Committee, Drs. J. E. Kimball, of Portland, and W. P. Watson, of Gorham. Dr. A. S. Thayer was elected Treasurer for five years, and Dr. C. D. Smith was, last year, made recording secretary for a term of ten years. Dr. A. L. Hersey, of Oxford, is to give the annual oration next year.

The meeting in 1884 will be held in Portland on the second Tuesday of June; and, as a committee on banquet was appointed, it is thought that the Association may devote an evening next year to purely social enjoyment.

LETTER FROM HONOLULU, HAWAIIAN ISLANDS.

MR. EDITOR,—Honolulu and the Hawaiian Islands have been so thoroughly written up in the daily press of late, that there are few people in our country who are not conversant with them commercially and politically, but there are many other interesting points which have only been occasionally touched upon, and a brief review of some of them may not prove inappropriate in the JOURNAL.

The discovery of the Hawaiian group of islands is generally accredited to Captain Cook who first visited them in 1778, but a careful inquiry elicits the fact that they were discovered many years previous by Gaetana, a Spanish navigator.

These islands lie just within the northern tropic, well out in the bosom of the broad Pacific, and are swept constantly from April to November by the northeast trade-winds. They are all of volcanic formation, and each one has several extinct craters, though Hawaii boasts the only active volcano, the celebrated

Kilauea. The great altitudes of the majority of the islands afford climates varying from frigid to tropical, and the cooling effect of the trade-winds naturally make the windward exposures much fresher than the sheltered portions. The average annual sea-level temperature throughout the group is about 77° F.

Honolulu, unfortunately, is situated upon the sheltered or lee side of the island of Oahu, and is consequently much warmer than many other towns in the kingdom. The trade-winds, however, are not entirely cut off, a goodly breeze generally sweeping through the *Pali*, or low place in the mountains, to the rear of the city. During the summer comparatively little rain falls in the city itself, though the mountains and high hills behind experience a shower nearly every afternoon; but from November to April southerly winds, called *Konas*, are apt to blow for a week at a time, bringing heavy rains, and causing langour, atrabiliousness, and even serious illness among the inhabitants.

Upon the whole, however, the general climate of the islands is very salubrious, and is exempt from the usual intertropical influences so fertile in disease production.

Honolulu being the metropolis of the kingdom, it is, of course, here that the great majority of foreigners congregate. The whole place seems to be in the hands of Americans, and they have so thoroughly Americanized it, that were it not for the tropical vegetation, one could easily imagine it a New England town. Strangers visiting this place will find the Hawaiian Hotel a very comfortable house to live in, but especially would I recommend the charming little cottages attached to it. In the other islands, unfortunately, there are few public houses, and the traveler has to depend chiefly upon individual hospitality for a place to put his head.

The city of Honolulu now contains about 16,000 inhabitants, of which nearly six thousand are foreigners. The mortality for 1880 was simply frightful, having been 72.62 per 1000; the high rate, however, coming entirely from the native element. The birth-rate in Massachusetts for the same year was 24.8 per 1000; in Honolulu 87.3. Death-rate in Massachusetts under five, 19.8; in Honolulu, 172.6. The Hawaiian statistics are not compiled in as careful a manner as they might be, so these comparisons will have to be taken with a certain amount of reserve.

The remarkable decrease in the native population of the Hawaiian Islands since the visit of Captain Cook in 1779 affords food for thoughtful study. Cook asserted that there were 400,000 people in the entire group, but it seems probable that this estimate was too high, and that really there were not more than 200,000. In a century this dense population has dwindled to 40,000, an annual decrease of nearly two per cent., and as the same exterminating causes continue to act, the probabilities are that the Kanaka will become extinct in twenty or thirty years more, or at least be as much of a curiosity in his own islands as the red man is upon our own Atlantic shores.

This slow but sure extinction of the Hawaiians has been the result of numerous causes, many of which are and have been easily remediable. It is more than probable that the diminution had begun before the time of Cook's first visit; at all events it has been in active operation ever since.

When the Boston missionaries first settled among the natives they found infanticide practiced to an alarming extent, mothers deliberately smothering, strangling, or burying alive their newly born. Mrs.

Judd,¹ the wife of that Dr. Judd to whom the Hawaiians owe their present form of government, mentions the frightful extent to which infanticide was carried in 1828, and records a case under her own observation where a mother was known to have buried alive eight out of ten children born to her. Civilization, however, has somewhat refined the native taste, so that abortion has superseded the more barbarous method, and the manner in which they induce it is well worth relating. The unfortunate woman is placed upon her back on the floor, and the officiating *Kahuna*, or medicine woman, taking a stone in either hand, proceeds to knead and squeeze the abdomen, endeavoring to get the uterus between the stones. Next she gets upon her victim's abdomen with her knees, and walks all over it so to speak. This violence generally brings on flooding, and in a short time abortion, but alas! frequently at the expense of the patient's life, though in one case which was cited to me dumb-bells replaced the stones in the operation, great violence being done, and yet the woman went on to term and gave birth to a healthy child.

Syphilis spread rapidly among the natives after the visits of the early navigators, and is said to have impregnated the entire race, destroying many, and rendering hosts sterile. Immorality, the curse of this ethnic stock, has, of course, greatly promoted the extension and perpetuation of syphilis and materially increased the number of barren women.

Leprosy, introduced by the Chinese about thirty years ago, has destroyed many of the Kanakas, and is steadily extending its loathsome and deadly hold. It is estimated that there are about 1600 lepers in the kingdom, 600 of whom are confined to the leper colony on the island of Molokai, and 100 in the leper hospital at Honolulu. Of the 900 at liberty the majority live in and around the metropolis. These lepers are constantly marrying non-lepers, and there seems to be no fear of the disease either among the pure Polynesians or half-castes. Foreigners generally experience immunity from it, though the man Derby, who turned up recently in Salem, Mass., was a well-known leper here for many years. He enjoyed the kind considerations of a native leper woman during the greater part of his residence in the islands, and it was from her that he contracted the disease.

Dr. Fitch, now in charge of the leper establishments, asserted a year ago that leprosy was merely the "fourth stage" of syphilis; he has recently modified this statement, and simply says it is a consecutive form. He treats all lepers upon the postulate that they are syphilitics, giving them a hearty dosing of the iodides and mercurials. There is no question but that the patients improve under this regimen; and further, that when taken in its incipency the disease is often apparently arrested. The good effects of this destructive treatment are easily explained when it is remembered that pathologically the lesions of syphilis and leprosy are identical, and essentially due in each case to local cell proliferation. From the foregoing facts it would appear that a bacillus is far from being the pathological entity of leprosy, Hansen, Cornil, and others to the contrary notwithstanding.

Epidemic diseases have been peculiarly fatal in these islands, especially small-pox, which, though it has only made its appearance twice, first in 1853, and again in 1881, has carried off thousands. Its first introduc-

tion was from California; the second from China by the Coolie ships. In 1848 terrible epidemics of measles, whooping-cough, and influenza occurred, thousands being swept away, and such consternation produced that ever since 1848 has been alluded to as "the death year."

The very unequal struggle which the semi-civilized and naturally indolent Hawaiian has to maintain with the vigorous, fast-coming white man is gradually but inevitably exemplifying Darwin's doctrine of the survival of the fittest.

Finally, nautical predilections and rapidly increasing intemperance contribute not a little toward extinguishing the last smoldering fires of this Polynesian life.

As the native disappears the foreigner takes his place, large numbers of Americans, Portuguese, and Chinese constantly seeking homes in the isles of the Kamehamehas'. The decrease of the native population from 1872 to 1878 was 4023, whereas the increase of foreign population for the same period was 5111.

Situated in the northern suburbs of Honolulu, and at the foot of an extinct crater, fancifully called the "Devil's Punch-Bowl," is the Queen's Hospital, completed in 1861 by Kamehameha IV. The original building, constructed of coral stone, only contained ninety-two beds, but in 1876 a small, detached wooden building was erected for the accommodation of foreigners, and in 1879 a brick addition was put on to the west end of the old structure for administrative purposes. The hospital appointments are by no means in consonance with modern ideas, but serve the purpose well enough in this mild climate. The daily average of occupied beds is about seventy-five. The grounds are spacious, picturesque, and well cared for, forming a charming retreat for convalescent patients. Drs. McKibbin and Trousseau are the medical officers, and the institution is in charge of the apothecary during their absence.

Honolulu, being so accessible from San Francisco, is naturally overrun by doctors, but, thanks to the fictitious values produced by the reciprocity treaty, prices are high, and all these gentlemen seem to be making a good living. A license to practice is easily obtained, the simple exhibition of a diploma from a chartered medical college being taken as sufficient evidence of competency. The superstitious credulity which so largely dominates the native mind would make this place an *El Dorado* for the enterprising quack, but, fortunately, he has not yet struck the lead.

The proximity of the Hawaiian Islands to the Pacific coast, their importance to us commercially and strategically, and the rapid disappearance of the Kanaka race make it safe to predict that they will be absorbed into the Union at no very distant date.

Very truly yours,

ARTHUR C. HEFFENGER, M. D., U. S. N.

UNITED STATES STEAMSHIP LACKAWANNA, }
March 21, 1883.

— Of the 1865 visits made during the last quarter by the night medical service in Paris 55 were upon cases of croup, 9 of choleraic diarrhoea, 24 of strangulated hernia, 67 of abortion, 258 of parturition, 69 of convulsions, 69 of hæmorrhage, 39 of fracture or dislocation, 14 of burns, 15 of poisoning, 2 of suicide, and 1 of hydrophobia.

¹ Honolulu. Sketches of Life in the Hawaiian Island.

PRAGUE.

BOSTON, June 18, 1883.

DEAR SIR,—At this season of the year, when so many of your readers are about starting on a European trip, a few facts concerning the advantages for the study of obstetrics in the city of Prague may not prove uninteresting.

As every one knows, there is located there one of the finest lying-in hospitals in the world,—a hospital in which more than three thousand cases are treated yearly. To this hospital students are freely admitted, and Americans especially receive a cordial welcome. The cases as they are received are equally divided among three clinics, two of which are open to physicians and students, the remaining one being reserved for the instruction of midwives.

The *modus operandi* of gaining entrance to the hospital is extremely simple, the expense attending the process ridiculously small, and the opportunities offered disproportionately great. One has merely to visit the first assistant of either clinic and say that he desires to study in his wards. He writes a request to the Herr Director to assign a bed in the caserne, a fee of ten florins is paid, and the applicant is free to come and go as he likes. Besides this, one is of course expected to pay the professor or the assistant something for the privilege, and this is done by taking a private course of lectures and demonstrations, at a maximum cost of twenty-five florins (ten dollars).

The payment of the ten florins mentioned above is for the privilege of occupying a bed in the students' room. Here one can live quite comfortably, being called to every case by means of an electric bell connecting with the delivery ward. One bell indicates a case to examine, two bells a delivery, and three bells some abnormal or operative case.

In the delivery ward it is allowable to examine every case with as much minuteness and as frequently as desired. One can take charge of the delivery in any or as many cases as he may see fit. Opportunities are had to apply forceps and to do the other *ordinary* obstetric operations.

It may be remarked by some that the number of cases to be seen in Vienna is much larger. True, but when it is remembered that in Prague one has not to contend with a large number of students, each eager to get the best place when any interesting case is to be seen, and each trying to bribe a little higher than any one else in order to obtain some advantage over his fellows, it will be evident that all the advantages are not on one side.

In closing I desire to call particular attention to the fact that, in consequence of the increased influx of foreigners during the latter part of the summer, it has been decided to give one or more courses of lectures on operative and clinical obstetrics in the *English language*. Dr. Rubeska, first assistant in the obstetrical clinic of Professor Streng, will give such a course at such time as the number of English-speaking students shall warrant it, probably about the middle of August. At about the same time Dr. Michl, first assistant of Professor Weiss, will give an English course on surgery.

I take great pleasure in recommending these two gentlemen as highly competent instructors, genial companions, and as sufficiently proficient in our own language to make their courses extremely interesting and valuable to any who may desire to make a study of those particular branches.

Hoping that these few facts, thus briefly stated, may prove of interest and perhaps of benefit to some,

I remain, dear sir, very sincerely yours,

RUFUS A. KINGMAN, M. D.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM JUNE 15, 1883, TO JULY 6, 1883.

TILTON, HENRY R., major and surgeon. Granted leave of absence for four months. Paragraph 7, S. O. 136, A. G. O., June 14, 1883.

GORGAS, W. C., first lieutenant and assistant surgeon. The leave of absence granted in paragraph 5, S. O. 51, C. S., Department of Texas, extended one month. S. O. 63, Military Division of the Missouri, June 19, 1883.

WYETH, M. C., first lieutenant and assistant surgeon. Assigned to duty at Fort Maginnis, M. T. Paragraph 2, S. O. 103, Department of Dakota, June 14, 1883.

SMART, CHARLES, major and surgeon. Assigned to duty in the office of the Surgeon-General United States Army, and in addition to his duties in the Surgeon-General's office will continue to serve as a member of the National Board of Health. Paragraph 8, S. O. 147, A. G. O., June 27, 1883.

BLAIR, VICTOR, captain and assistant surgeon. Assigned to duty as post surgeon at Fort Sisseton, D. T. Paragraph 1, S. O. 102, Department of Dakota, June 13, 1883.

WINNE, CHARLES K., captain and assistant surgeon. Assigned to duty as post surgeon at Fort Winfield Scott, California. Paragraph 1, S. O. 69, Department of California, June 19, 1883.

WORTHINGTON, JAMES C., captain and assistant surgeon. Assigned to duty at Cantonment on the Uncompahgre, Colorado. Paragraph 4, S. O. 128, Department of the Missouri, June 21, 1883.

EVERTS, EDWARD, first lieutenant and assistant surgeon. Relieved from duty at Fort Coeur d'Alene and assigned to duty as post surgeon at Fort Lapwai, Idaho. S. O. 81, Department of the Columbia, June 14, 1883.

STRONG, NORTON, first lieutenant and assistant surgeon. Relieved from operations of paragraph 2, S. O. 42, C. S., Department of the Platte, and assigned to duty with Battalion Infantry now on duty between Forts Thornburgh and Bridger, Wyoming. Paragraph 2, S. O. 83, Department of the Platte June 21, 1883.

HEGER, A., major and surgeon. Relieved from the further operation of paragraph 9, S. O. 35, C. S., Department of Texas, and will return to his station, Fort Clark, Texas. Paragraph 2, S. O. 69, Department of Texas, June 25, 1883.

HAVARD, VALERY, captain and assistant surgeon. Assigned to duty with expedition to complete the survey of the country west of the Rio Pecos, Texas. Paragraph 8, S. O. 68, Department of Texas, June 22, 1883.

RAYMOND, HENRY L., first lieutenant and assistant surgeon. Granted leave of absence from July 14, 1883, to September 1, 1883, with permission to go beyond sea, and resignation accepted to take effect September 1, 1883. S. O. 150, A. G. O., June 30, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE TWO WEEKS ENDING JULY 7, 1883.

KERSHNER, E., surgeon, detached from the Navy Yard, New York, July 1st, and ordered to the Receiving Ship Colorado, New York.

CRAIG, T. C., assistant surgeon, detached from the Colorado, July 1st, and ordered to the Naval Hospital, New York.

BRYAN, J. H., assistant surgeon, detached from the Naval Hospital, New York, and ordered to the Museum of Hygiene, Washington, D. C.

HENEBERGER, L. G., passed assistant surgeon, detached from the Museum of Hygiene and ordered to the Navy Yard, New York.

BRANSFORD, J. T., passed assistant surgeon, detached from special duty, Washington, D. C., and ordered to temporary duty at the Naval Academy, Annapolis, Md.

LEACH, T. W., medical inspector, detached from the U. S. S. Tennessee, and as Fleet Surgeon of the North Atlantic Station and placed on sick leave.

RHOADES, A. C., medical inspector, detached from the Naval Academy and ordered to the U. S. S. Tennessee and as Fleet Surgeon of the North Atlantic Station.

REPORTED MORTALITY FOR THE WEEK ENDING JUNE 30, 1883.

Deaths reported 2771 (no reports from New Orleans and District of Columbia): under five years of age 1402: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 834, diarrhoeal diseases 489, consumption 303, lung diseases 187, diphtheria and croup 111, scarlet fever 81, measles 49, typhoid fever 36, malarial fevers 21, cerebro-spinal meningitis 15, whooping-cough 15, erysipelas eight, puerperal fever six, small-pox three. From *measles*, New York 18, Boston and Baltimore five each, Brooklyn four, Chicago and Nashville three each, Philadelphia, St. Louis, Pittsburg and Lynn two each, Cincinnati, Worcester, and Chelsea one each. From *typhoid fever*, Philadelphia eight, Chicago seven, New York five, Brooklyn, Boston, St. Louis, and Cincinnati two each, Baltimore, Pittsburg, Lowell, Fall River, Salem, New Bedford, Gloucester, and Westfield one each. From *malarial fevers*, New York eight, Brooklyn seven, St. Louis three, Chicago, Baltimore and Charleston one each. From *cerebro-spinal meningitis*, New York, Chicago, Baltimore, and Milwaukee two each, Philadelphia, Boston, Providence, New Haven, Worcester, Peabody, and Milford one each. From *whooping-cough*, New York four, Philadelphia and Baltimore three each, Brooklyn and Chicago two each, St. Louis one. From *erysipelas*, New York four, Philadelphia two, St. Louis and Cincinnati one each. From *puerperal fever*, Cincinnati two, Philadelphia, Boston, Baltimore, and Cambridge one each. From *small-pox*, Philadelphia two, St. Louis one.

Twenty-nine cases of small-pox were reported in St. Louis, Buffalo three, Baltimore one; measles 54, scarlet fever 21, diphtheria 19, and typhoid fever four in Boston; scarlet fever five, and diphtheria three in Milwaukee.

In 29 cities and towns of Massachusetts, with an estimated population of 936,023 (estimated population of the State

1,922,530), the total death-rate for the week was 16.49 against 16.97 and 21.06, for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending June 16th, the death-rate was 18.7. Deaths reported 3083: acute diseases of the respiratory organs (London) 203, measles 105, scarlet fever 75, diarrhoea 68, whooping-cough 62, fever 32, diphtheria 22, small-pox (London three, Hull and Newcastle one each) five. The death-rates ranged from 12.2 in Norwich to 26.5 in Newcastle-on-Tyne; Leicester 14.9; London 16.9; Brighton 18.8; Cardiff 19.7; Sheffield 20.1; Liverpool 23.5; Manchester 26. In Edinburgh 16.8; Glasgow 30.6; Dublin 23.4.

For the week ending June 16th, in 168 German cities and towns, with an estimated population of 8,553,682, the death-rate was 28.3. Deaths reported 4654; under five years of age, 2394; consumption 651, lung diseases 510, diarrhoeal diseases 247, diphtheria and croup 154, measles and rhelein 116, scarlet fever 70, typhoid fever 43, whooping-cough 39, puerperal fever 23, small-pox (Heilbronn two, Danzig, Bromberg, Spandau, and Frankfurt one each), six, typhus fever (Frankfurt on M. one) one. The death-rates ranged from 13 in Braunschweig to 38.8 in Cologne; Königsberg 28.3; Breslau 38.6; Munich 37.3; Dresden 25.8; Berlin 33.7; Leipzig 31.5; Hamburg 27.3; Frankfurt on M. 26.2; Metz 18.6.

For the week ending June 16th, in the Swiss towns, there were 28 deaths from consumption, diarrhoeal diseases 22, lung diseases 15, measles seven, typhoid fever seven, diphtheria and croup four, whooping-cough two, erysipelas two, puerperal fever one. The death-rates were at Geneva 11.3, Zurich 14, Basle 16.7, Berne 30.5.

The meteorological record for the week ending June 30th, in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

Date.	Barom-eter.	Thermom-eter.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

FISKE FUND.

THE Trustees of the Fiske Fund, at the annual meeting of the Rhode Island Medical Society, held at Providence, June 21, 1883, announced that they had made no award on the subjects proposed for the present year.

They propose the following subjects for the year 1884:—

(1.) The Origin and Progress of the Malarial Fever now prevalent in New England.

(2.) Original Investigations in Household Hygiene.

For the best essay on either of these subjects worthy of a premium they offer the sum of three hundred dollars.

Every competitor for a premium is expected to conform to the following regulations, namely:—

To forward to the Secretary of the Trustees, on or before the first day of May, 1884, free of all expense, a copy of his dissertation, with a motto written thereon, and also accompanying it a sealed packet, having the same motto inscribed upon the outside, and his name and place of residence within.

Previously to receiving the premium awarded the author of the successful dissertation must transfer to the Trustees all his right, title, and interest in and to the same for the use, benefit, and behoof of the Fiske Fund.

Letters accompanying the unsuccessful dissertations will be destroyed by the Trustees, unopened, and the dissertations may be procured by their respective authors if applications be made therefor within three months.

JOB KENYON, M. D., River Point,
OLIVER C. WIGGIN, M. D., Providence,
HORACE G. MILLER, M. D., Providence,
Trustees.

CHARLES W. PARSONS, M. D., Providence,
Secretary of the Trustees.

TRI-STATE MEDICAL ASSOCIATION.

THE ninth annual meeting of the Tri-State Medical Association will be held in Indianapolis, September 18th, 19th, and 20th. The work is already far advanced, and the title of each paper should be sent in at once. Papers must not exceed twenty-five minutes.

It is also the rule that each physician who registers must be a member of a local or State society in good repute. All such are invited.

Notice of papers or cases to be presented may be sent to the Chairman of the Committee on Programme, Dr. J. L. Thompson, Indianapolis, to the Secretary, Dr. G. W. Burton, Mitchell, Ind., or to the President, Dr. William Porter, St. Louis.

St. Louis, June 29, 1883.

ERRATUM.—Page 589, second column, of JOURNAL, June 21st, in Dr. Johnson's reply to a toast, for "higher rational education" read "higher medical education."

APPOINTMENTS.—Thomas Dwight, M. D., has been appointed Professor of Anatomy in the Harvard University Medical School.

Drs. C. M. Green and Robert B. Dixon have been appointed Assistant Physicians to the Boston Lying-In Hospital.

THE honorary degree of M. A. has been conferred upon Dr. Henry A. Martin by Dartmouth College.

BOOKS AND PAMPHLETS RECEIVED.—Handbook for Hospitals. No. 32. State Charities' Aid Association. New York. G. P. Putnam's Sons. 1883.

The Forty-Fourth Annual Report of the Superintendent of the Boston Lunatic Hospital to the Board of Directors for Public Institutions. For the Year ending April 30, 1883.

Constituents of Tubercles, and Explanations regarding Them. By Rollin R. Gregg, M. D.

Woman's Medical College of Pennsylvania, Philadelphia. Annual Announcement, May, 1883.

Army Hospital Services Inquiry Committee. Report of a Committee appointed by the Secretary of State for War to inquire into the Organization of the Army Hospital Corps, Hospital Management, and Nursing in the Field, etc. Presented to both Houses of Parliament by command of Her Majesty. London. 1883.

Hospitals, Infirmarys, and Dispensaries. Their Construction, Interior Arrangement, and Management. With Descriptions of Existing Institutions and Seventy-Four Illustrations. By F. Appert, M. D., M. R. C. P. L. Second Edition, Revised and Enlarged. London: J. & A. Churchill. 1883.

How can we Obtain and Preserve the Best Eyesight and Hearing? A Paper read before the Sanitary Convention at Greenville (Mich.), April 11, 1882. By Leartus Connor, A. M., M. D., of Detroit. (Reprint.) 1882.

Catalogue of the Albany Medical College. Medical Department of Union University. Fifty-Second Session. 1882-83. Albany. 1883.

Du Diagnostic de l'Ectopie Rénale. Par le Dr. Frédéric Buret. Publications du Progrès Médical. Paris. 1883.

Cases from Practice. By H. V. Sweringen, M. D., Fort Wayne, Indiana. (Reprint.) 1883.

Ninth Annual Announcement of Columbia Medical College, of Columbus, Ohio. Session of 1883-84.

Twenty-Third Annual Announcement of the Bellevue Hospital Medical College, 1883-84.

A Treatise on the Diseases of the Eye. By J. Soelberg Wells, F. R. C. S., Doctor of Medicine of the University of Edinburgh, etc. Fourth American from the Third English Edition, with Copious Additions. By Charles Stedman Bull, A. M., M. D. Philadelphia: Henry C. Lea's Son & Co. 1883.

Fifth Annual Report of the State Board of Health of the State of Rhode Island for the Year ending December 31, 1882. Including the Report upon Births, Marriages, and Deaths in 1881. Providence. 1883.

Wood's Library of Standard Medical Authors. The Diseases of Women. A Manual for Physicians and Students. By Heinrich Fritsch, M. D. Translated from the German by Isidor Furst. With 159 Wood Engravings. New York: William Wood & Co. 1883.

The International Encyclopædia of Surgery. A Systematic Treatise on the Theory and Practice of Surgery by authors of Various Nations. Edited by John Ashurst, Jr., M. D., Professor of Clinical Surgery in the University of Pennsylvania. Illustrated. In Six Volumes. Vol. III. New York: William Wood & Co. 1883.

Lectures.

CLINICAL LECTURE ON SOME OF THE CAUSES OF STERILITY, AND THEIR TREATMENT.

DELIVERED AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

BY T. GAILLARD THOMAS, M. D.,

Clinical Professor of Gynaecology.

GENTLEMEN, — Three cases of sterility having presented themselves by accident at the clinic to-day, I will avail myself of the opportunity to give you a practical illustration of some of the causes and of the treatment of this condition. If your experience when you are in practice is anything like what mine has been, however, you will undoubtedly find that in general the results of the treatment of sterility are very unsatisfactory. Perhaps out of twenty cases you may have one or two successes, and your professional neighbors may be led to form a high opinion of your skill, because you will be sure to publish the one or two successes, but will take good care not to say anything about the eighteen or nineteen failures. In a London review of one of the editions of my work on diseases of women, the opinion was expressed that it showed an extraordinary barrenness of results in the treatment of sterility, and that these were much better on the other side of the water. Yet if one were to examine into the methods resorted to there it would be found that precisely the same means were employed which were recommended in my book.

There is only one way in which any success whatever can be achieved in the treatment of this troublesome affection, and that is to study each particular case on its own merits, and thus avoid the grievous error of falling into any routine method.

In doing this one will sometimes find that there is some constitutional ailment in the husband which prevents conception; in other cases, that although there is no constitutional trouble, the local results of a specific urethritis give rise to the difficulty, and in others, again, that the husband is impotent.

The first patient that I bring before you is Mrs. J., who is twenty-seven years of age, and has been married eight years, but has never been pregnant, although she is anxious to have children. She says that she enjoys good health, with the exception of having more or less pain in her head and back, and marked irregularity in her monthly sickness. Her menses come on only once in every three or four months, and the flow is even then very scanty, at the most lasting only twenty-four hours; while it is accompanied by very severe bearing-down pain. She also suffers considerably from leucorrhœa.

From the above history we can say at the outset that it looks as if there were something wrong about the woman herself, rather than her husband, which prevents her from bearing children. The results of a physical examination are as follows: The patient having been placed on the back and the finger passed up into the vagina, it was found that the cervix was in its normal position, but the moment it was touched it was ascertained that there was something peculiar about it. The os, instead of being of the natural size, was only that of a small pin-hole. The finger was now carried up higher and a mass was found behind the cervix

pressing upon the rectum. By conjoined manipulation it was ascertained that the body of the uterus was absent from its natural position, and the patient then being placed upon her side and a Sims speculum introduced, a very small probe, bent backward, was passed down into the uterine cavity. It was thus demonstrated beyond a question that the mass back of the cervix was the body of the uterus, which was in a state of marked retroflexion. We have found, therefore, an ample explanation of the sterility in this case. It is true that many women suffering from retroflexion do bear children (though they generally have one or two miscarriages first), but when this is the case, you will not find the os in the condition which we have noted here.

In answer to special inquiries, the patient informs me that she did not begin to menstruate until she was eighteen years of age, and that she had to have the mouth of the womb opened by a slight operation. In these cases of narrow cervix the blood gets dammed up, causing great pain, which is at length relieved by the expulsion of a small clot. After a time, as the result of this repeated damming up of blood in the uterine cavity, the organ becomes retroflexed. We then have an additional factor in the production of dysmenorrhœa, because the bending of the uterus gives rise to spasmodic spasm of the sphincter muscular fibres of the cervix, and spasmodic dysmenorrhœa is thus added to the obstruction. We have, therefore, three causes for the trouble in this case: First, a narrow cervix, preventing a free egress of menstrual blood and causing a "halooning" of the uterus at every period; second, retroflexion, occasioning spasm of the cervical muscle; and, third, a constant engorgement of the uterus with blood, resulting in the production of uterine catarrh.

Before referring to the treatment appropriate here, I would warn you never to promise a cure in such a case as this. Simply tell your patient that you see a number of conditions which appear to prevent pregnancy, that you think you can remove them, and that when this has been done the chances are that her dysmenorrhœa will be relieved, and that she will bear children. The treatment must consist in overcoming the chain of morbid conditions discovered, the narrow cervix, the bent uterus, the uterine spasm, and the uterine catarrh. It would be better, however, not to commence their removal in the order in which they have occurred. Such a patient should enter the hospital, and, having been put to bed, should be treated first of all with the hot water douche and laxatives. Then three times a week the uterus should be restored to its normal position by means of the sound. It is probable that her next menstrual period would be less painful than heretofore, and at the end of it the cervix should be held with a tenaculum, and three incisions, each cutting the sphincter muscle to the depth of one eighth of an inch, should be made with the Sims' knife. This having been done thoroughly, a glass stem should be pushed up into the uterus and maintained in position by means of an Albert Smith pessary (provided with a little cup in which the lower extremity of the stem can rest), which will also keep the uterus in position. After the operation the patient should be placed in bed and given an opiate. She should remain in bed for ten or twelve days, and have a carbolized vaginal injection three times a day. The glass stem may be kept in the uterus until after the next menstrual

¹ Reported for the Boston Medical and Surgical Journal.

period if it is thought desirable; but it should at all events be taken out then. By this time it will probably be found that the uterine engorgement has disappeared and the leucorrhœa has diminished; while the unnatural narrowness of the cervix has been removed entirely. (The glass stem should be somewhat larger than the normal canal.)

The patient can then be allowed to go home wearing the stem and Albert Smith pessary. Twice a week the stem should be removed, and a probe wrapped in cotton dipped in pure carbolic acid passed up to the fundus. This application, which covers the mucous membrane with a whitish coating, can be made in the office. It is accompanied with no danger whatever, and I regard the carbolic acid as of much more service than iodine, zinc, or alum when used in this way. In from six months to a year the glass stem might be left off, and there would then be a chance of impregnation. It would be only a chance, you must remember, but I know of no better plan of treatment than that of which I have now given you the outline. Our premises here, I think, are undoubtedly correct, as I have seen the same conditions in hundreds of cases. In this particular instance, however, I should not feel very hopeful of overcoming the sterility for the reason that the facts that the patient did not commence to menstruate until she was eighteen and that the flow only comes on every three months naturally make me suspect that the ovaries may be at fault as well as the uterus.

Our next patient is Mrs. Elizabeth L., born in Germany, and nineteen years old. She has been married four years, and has never had any children, but thinks she had one miscarriage. She complains of pain in the region of both ovaries, which begins four days before the menstrual flow, continues through it, and lasts for a day or two after it disappears. She also suffers from the pain in the top of the head, which has been called uterine headache, and says she has never felt well since she had the miscarriage, which occurred about a year after her marriage.

Each case of sterility must be studied by itself, and this is of an entirely different character from the last. When a vaginal examination was made here the finger failed to reach the cervix in its normal positions, but it was afterwards found much higher up than it ought to have been, while a mass continuous with this was found pressing down upon the rectum. The introduction of the probe showed that this was the retroverted uterus, the axis of the organ being completely changed. From the os uteri could be seen, through the speculum, a plug of viscid mucus hanging, looking like white of egg, and so tenacious that it was difficult to cleanse the cervix. When the mucus was removed a condition was observed beneath resembling that of granular lids, and the surface bled freely when touched with the small, dry sponge used to cleanse it. Both ovaries were enlarged to twice the normal size.

Here is a young woman who was perfectly well up to the time of a miscarriage, occurring a year after her marriage. She very likely got up on the third or fourth day, and in all probability, unfortunately, with the consent of her physician, if she had one. The uterus being heavy fell over backwards, and the ligaments were pulled upon, the traction on the broad ligaments preventing the return of venous blood. The pathological chain in this case is, then, retroversion with engorgement of the uterus, endo-metritis, chronic inflammation of the Nabothian follicles, and sym-

thetic engorgement of the ovaries. It is estimated by Tyler Smith that there are two thousand mucous follicles in the cervix, and it is a question whether chronic inflammation of these is ever cured.

The treatment that I would advise here would be to restore the uterus to its normal position, and put in a retroversion pessary, after which the mucus should be carefully removed from the whole uterine tract two or three times a week, and the surface painted over with pure carbolic acid. Within the os internum this is undoubtedly the safest as well as the best application, and I know of no other chemical which, thus applied, is not liable to produce pelvic cellulitis or peritonitis occasionally. Judging from my past experience, however, I should pronounce this even a more doubtful case than the other, as the sterility depends upon a cause well nigh incurable.

Our last patient to-day is Mrs. Rose G., twenty-four years old, and a native of Austria. She has been married six years, but has never been pregnant, and it is on account of her sterility that she comes to consult us. She is regular in her monthly periods, but sometimes they are accompanied with much more pain than at others.¹ The flow lasts from four to six days. When the finger was introduced into the vagina the cervix was found to be long and conical, and the os very small. There was no leucorrhœa or other abnormal condition. The probe was passed with great difficulty on account of the small size of the os, and I have no doubt that in this case the peculiar formation of the cervix is the cause of the sterility. It is a cause which has been recognized by every writer within the last few years, and I think that our patient can, probably, be entirely cured.

In aggravated cases of this kind, where the neck projects very markedly, and is decidedly conoidal, amputation of the cervix is required, but in the present instance I think the cervix hardly long enough for this, and would advise the operation by bilateral incisions for its enlargement. If this should be done it is highly probable that impregnation would result, but it is by no means a certainty. I have thus been able to present to you some cases illustrating a few of the numerous causes of sterility, and it gives me pleasure to conclude with one in which it is possible to make a little better prognosis than in the other two.

CASES IN PRACTICE.²

BY GEORGE STEDMAN, M. D.

TWO CASES OF ABORTION, ONE PRESENTING UNUSUAL DIFFICULTIES IN THE POST MORTEM, THE OTHER IN THE ANTE MORTEM DIAGNOSIS OF THE CAUSE OF DEATH. A CASE OF LAUDANUM POISONING IN AN INFANT ONE DAY OLD. RECOVERY.

THE following cases seem to me of interest: the first showing the difficulty in determining the exact

¹ It is curious how greatly the pain suffered by women during menstruation varies at different times and under different circumstances. Some women who have dysmenorrhœa at the sea-shore are free from it in the mountains, and *vice versa*, and I have known ladies from Cuba who suffer from it here, but not at home. When the system is in a depreciated condition from malaria or other cause dysmenorrhœa is liable to occur in those who are at other times free from it.

² Read before the Boston Society for Medical Observation, March 19, 1883.

cause of death, and consequently the uselessness of commencing a prosecution, although there being a moral certainty that the death was caused by an attempt at criminal abortion, the second case being also a case of undoubted criminal abortion, but presenting difficulties in the way of diagnosis to the attending physician.

October 30, 1882, I was acting as medical examiner in the northern district of Suffolk County, and was summoned at about six o'clock in the afternoon to attend a case of sudden death. I immediately answered the call, and was directed to the office of a certain doctor, where I found lying upon the lounge the dead body of a young woman. In answer to my questions the doctor told me that he did not know who she was or where she belonged; that he had never seen her but once before, when, about ten days previously, she had come to his office, and, upon her complaining of "past menses," he had prescribed a simple remedy of aloes and iron; that he had not again seen her until the day of her death, when, about four o'clock in the afternoon, she appeared at his office, and, coming in, immediately began to complain of dizziness. He laid her upon the lounge, fanned her, and offered water to her, but she could not swallow. He called in assistance, but all to no purpose; the woman died within half an hour after entering the office.

The body was removed to the morgue and placed upon ice; the autopsy was made the following morning by Dr. W. F. Whitney and myself, the microscopical examination being made by Dr. Whitney.

Autopsy eighteen hours after death.

Inspection. Rigor mortis present. Lividity of dependent portions of the body. Fatty tissue well developed.

Hymen absent.

Fourchette intact. Slight brown line from umbilicus to pubes.

Section. Blood everywhere in the body fluid and dark.

Skull thin.

Brain and Membranes. Veins of pia mater much injected. Brain substance firm. Puncta cruenta very abundant. Brain otherwise normal.

Diaphragm at fifth space.

Pericardium contained normal amount of fluid.

Heart. Both sides of the heart distended with dark fluid blood; bubbles of gas mixed with blood issued from the right side. Heart's substance and valves normal.

Pleura. One ounce serum in each cavity.

Right Lung bound to chest by old adhesions. Lungs did not fully collapse upon removal. Lower lobes darker in color and more distended than the upper. On section considerable quantity of fluid mixed with air issued from cut surface. Lower lobes contained more of this than the upper. Microscope showed blood-vessels to be filled with excessive amount of blood. Alveoli filled with serum and a few desquamated cells.

Kidneys normal, dark red; cortex and pyramids not sharply differentiated. Microscope showed blood-vessels to be filled with excessive amount of blood. Slight increase of interstitial tissue.

Spleen normal in size; dark red in color, firm; follicles distinct.

Pancreas and *supra-renal capsules* normal.

Stomach contained large amount of fluid and undigested food. Surface slightly reddened.

Intestines filled with dark faeces, in which were small yellowish lumps and seeds (lemon). Follicles of large intestine very prominent. Small intestine presented no unusual appearance except an increased redness of inner surface of duodenum at about its middle.

Contents of stomach and intestines retained for chemical analysis, and delivered to Dr. W. B. Hills.

Liver normal in size and color. Increase of blood in portal system.

Bladder normal, contracted, and empty.

Peritoneum normal.

Uterus size of man's fist; mouth slightly excoriated and patulous; cervical canal large, and comparatively small amount of mucus in it.

Cavity of uterus contained an embryo within its membranes of about the eighth to tenth week. Lying free in the cavity of the decidua was a fresh dark clot the size of the little finger; entangled in its meshes was a piece of choroid and decidua. In right ovary was a body the size of a cherry, bright yellowish in color, with a central translucent portion.

Diagnosis. General venous congestion; œdema of lungs; pregnancy of about the eighth to tenth week; ante-mortem hæmorrhage from laceration of the decidua.

Dr. Hills's report of his analysis of the contents of the stomach and intestines was negative as to the cause of death.

In the above account there certainly seems no really sufficient cause for death. All that can be said is that there was evidence of recent instrumental interference with the pregnant uterus; that this interference was doubtless intended to produce an abortion, and was the probable cause of death.

The second case was that of a young woman belonging in the Provinces, and who had recently arrived in Boston after a long and tedious sea-voyage. She was attended by Dr. George W. Galvin, who was called in on Thursday, February 1, 1883. He found her in bed, complaining of pain in the bowels, which she attributed to her constant vomiting while on the boat from Halifax to Boston. There was little tenderness and no tympanites. Pulse 84. She said she had menstruated somewhat profusely three days previously. There had been no chill, rigor, or fever, and considering the pain and tenderness due to the long-continued retching she was ordered an opiate and hot fomentations to the bowels. On February 4th, the bowels not having moved for several days, a cathartic of aloes and rhubarb was ordered, and this not operating an enema of warm water and turpentine was given; this also failing to produce the result desired opiates were again resorted to, together with warm applications. The patient was kept comfortable by these means for two days, and again injections and cathartics were resorted to, but without relief.

Vomiting commenced, the vomitus at first being composed apparently of gastric juice and bile, but the vomiting continued to increase in force until Thursday evening February 8th, when the matter vomited began to become darker in color and somewhat offensive until on Friday the vomitus was distinctly fecal. Drs. Harding and Stedman were called in to see the case, at which time the patient was very weak and still occasionally vomiting fecal matter. There was some tympanites, but not specially marked; also some abdominal tenderness.

There seemed to be a comparative dullness on percussion in the right iliac region, but very little tenderness shown by percussion or palpating. The patient died on the following night.

On section of the abdomen no intestinal obstruction was discovered, but there was a general peritonitis with pus formation.

The uterus was about the size of a pregnant uterus of about two and a half months.

Section of the uterus showed that it had recently contained an embryo, that there were evidences of the probable introduction of an instrument of some kind into the uterus, and that the peritonitis had been caused by the passage of irritating matter from the uterus through the Fallopian tubes to the peritoneal cavity.

The specimens were shown to Dr. F. W. Draper, under whose jurisdiction as medical examiner the case would come, and he agreed with me that the evidence of criminal malpractice was not sufficiently positive to warrant a prolonged official investigation.

In this case the symptoms so clearly pointed to intestinal irritation, with obstruction as a possible and perhaps probable cause, that the condition of pregnancy was overlooked, and not suspected until the time of the autopsy.

Although the following case has no connection with the former two, nevertheless I thought it might be of some interest as showing how persistent perseverance may sometimes be crowned by success.

On December 15, 1882, I was called to attend Mrs. G. in confinement. The labor was somewhat tedious, but progressed normally, and an eleven-pound boy was born. There was some difficulty in delivering the placenta, it being partially attached. This I afterward learned had also occurred at a previous confinement. Everything went on as well as could be expected, the mother being very much debilitated from too frequent pregnancies, she having had five children in a little over nine years. On the following day I was called at five o'clock in the morning to see the baby.

When I arrived at the house the baby was in a very severe convulsion, and I learned that at about three o'clock it had received an unknown quantity of laudanum—say several drops. The usual remedies were administered, such as mustard applications, warm baths, and coffee, but when the convulsive movements ceased the child also ceased to breathe and lay as if dead. I applied the stethoscope to the heart and found that it was beating very slowly and irregularly as follows: one—two, — one — two, — one — two, — one — two. I immediately commenced artificial respiration, and after a few moments again applied the stethoscope and heard the heart beating faster and regularly as follows: one, two, three, four, five, six, seven, eight, nine, ten, yet the child did not breathe, and I was encouraged to continue employing artificial respiration; finally the child gasped and commenced to breathe naturally. Everything went on nicely for about ten minutes, when the same proceedings were repeated, and after a few moments the child again breathed, and again in ten minutes there was another convulsion. I attempted to start up the respiration by the same means, namely, by placing my left hand to the back with the thumb and fingers in the axillæ, while with the right hand I grasped the thighs and legs, and by alternately extending and flexing the body of the child endeavored to pump air into the lungs. This time I was unsuccessful in restoring respiration, and I again lis-

tened with the stethoscope, and finding the heart's action failing I laid the child on the lap of an attendant, turned its head back as far as possible so as to clear the œsophagus, held the nose with the thumb and forefinger of the right hand, while I filled the lungs by blowing into the mouth, evacuating the air by compressing the abdomen and lower ribs with the left hand. The child breathed again. I now applied the stethoscope to the chest, and heard moist râles throughout the lungs, and with the idea of diminishing the amount of œdema I applied leeches, one over the sternum, and one to each side, and with the idea of diminishing a probable œdema of the brain one leech was also applied to the nape of the neck. The leech-bites were encouraged to bleed by application of warm-water cloths, and I calculated that nearly three ounces of blood was taken. I again listened, and discovered a marked diminution in the amount of fluid in the lungs, and it was noticed that the convulsions came less frequently; instead of every ten or fifteen minutes they occurred every twenty minutes, and then every half hour until three o'clock the following morning, the same process of blowing up being resorted to after each convulsion.

The baby was now pretty thoroughly blown up, the stomach and intestines being much distended; in fact, they could hold no more wind, for every time we blew into the child's mouth there was audible response from "the other end."

At five o'clock I lay down on the lounge by the side of the father, who was holding the child, and gave directions to be called should another convulsion occur. I was called at seven o'clock, but the convulsion was not so severe, and after the convulsive movements had stopped the child commenced to breathe without artificial aid. Brandy and beef tea were given from time to time by the rectum, and at eleven o'clock the following morning the child took the bottle, and convalescence was established.

A NOTE ON THE FÆCES OF STARCH-FED INFANTS.¹

BY N. A. RANDOLPH, M. D.,

Assistant Demonstrator of Physiology in the University of Pennsylvania.

THE series of experiments presented in the preceding paper² by Dr. Keating seems to me to be in the highest degree suggestive, for it is only rational to suppose that the development of the amylolytic ferment of the pancreatic juice is coincident with the appearance of the analogous salivary ferment. Inasmuch, however, as the food even in spoon-fed infants is retained but a short time in the mouth, and further, as the continued action of the saliva after it enters the stomach is as yet problematical, the only absolute control for such observations is afforded by an examination of the fæces.

Through the kindness of Dr. Keating I have been enabled to examine the stools of twenty-four starch-fed infants, of ages varying from forty-five days to eighteen months. Twenty-three of these children were fed upon cracker-dust, water, and condensed milk. The twenty-fourth received corn-starch boiled in milk.

¹ Read before the College of Physicians of Philadelphia, June 6, 1883.

² See page 3 in number of July 12th.

The freshly-evacuated fæces of each infant were carefully bottled and labeled, and a drop of a solution of iodine was added to a small portion of each specimen, which was then submitted to microscopical examination. Besides turning the starch blue, and indicating the presence of dextrine by a peculiar mahogany-red color, the iodine has the advantage of rendering any fats which may be present much more readily apparent. The reaction of each specimen was taken, but though this varied from acid to alkaline and neutral, no correlation between the reactions and the other properties of the specimens could be observed. A decoction of each was tested for glucose with freshly prepared Fehling's solution, but except in one instance no appreciable amount could be found.

The presence of starch was exceptional, and appar-

ently in no degree dependent upon the age of the child. The stools of eighteen out of the twenty-four children contained either no starch or but a trace, that is, no more than is frequent in the evacuations of a healthy adult upon a mixed diet. Six of these specimens were from children of three months or less, the youngest being but forty-five days old. In many cases the broken and empty cellulose envelopes of the starch granules were clearly discernible.

The six infants in whose evacuations a noteworthy amount of starch was present were aged respectively three, four, ten, thirteen, fourteen, and seventeen months. The eldest two were in very bad health.

The following is a tabular statement of the age, diet, and appearances of the fæces in the children forming the subjects of this study.

AN EXAMINATION OF THE FÆCES OF TWENTY-FOUR STARCH-FED INFANTS.

No.	Name.	Age.	Food.	Starch Present.	Remarks.
1	Savin.	45 days.	Condensed milk and cracker dust.	None.	
2	Jocker.	2 months.	Condensed milk and cracker dust.	Traces.	
3	McGettinger.	2+ months.	Condensed milk and cracker dust.	Traces.	
4	McGowan.	3 months.	Condensed milk and cracker dust.	Traces.	Twice examined; no fat before inunction; about ten per cent. after.
5	Ross.	3 months.	Condensed milk and cracker dust.	Traces.	
6	Hays.	3 months.	Condensed milk and cracker dust.	About one fourth starch.	
7	Soy.	3 months.	Condensed milk and cracker dust.	Traces.	
8	Henwich.	4 months.	Corn-starch and milk.	Traces.	
9	Moore.	4 months.	Condensed milk and cracker dust.	None.	Many broken cellulose envelopes. Evidences of potato surreptitiously given.
10	Conway.	4+ months.	Condensed milk and cracker dust.	Traces.	
11	Rosch.	5 months.	Condensed milk and cracker dust.	About one half starch.	
12	Anxier.	5+ months.	Condensed milk and cracker dust.	None.	
13	Schmits.	5+ months.	Condensed milk and cracker dust.	None.	Many bacteria.
14	McKinley.	6+ months.	Condensed milk and cracker dust.	None.	
15	Hall.	8+ months.	Bread and cracker food.	Traces.	Ten per cent. fat; had had inunctions.
16	Hensen.	10+ months.	Condensed milk and cracker dust.	More than normal.	
17	Divine.	18- months.	Condensed milk and cracker dust.	Twenty to thirty per cent.	
18	Croncia.	14- months.	Condensed milk and cracker dust.	Traces.	Many bacteria; evidences of potato surreptitiously given. Some glucose present and indications of dextrine; saliva was found to be inefficient.
19	Madden.	14 months.	Condensed milk and cracker dust.	Traces.	
20	Boyle.	14 months.	Condensed milk and cracker dust.	Ten per cent. starch.	
21	Glass.	14+ months.	Condensed milk and cracker dust.	None.	Sick.
22	Kinscher.	17- months.	Condensed milk and cracker dust.	None.	
23	Wood.	17- months.	Condensed milk and cracker dust.	Over three fourths starch.	Except a few large cells containing starch from potato.
24	Dane.	18 months.	Condensed milk and cracker dust.	Traces.	

The facts presented appear to justify the following conclusions:—

First, that *many* infants of under three months can digest starchy foods.

Second, that the individual variations in this regard are so numerous that no broad and general statement can be made as to the period at which infants *begin* to digest starches; and

Third, that the physician can be absolutely certain that a farinaceous ingredient in the diet of a young infant is beneficial only by an examination of the dejecta under such diet.

After the reading of the preceding paper Dr. Keating spoke of one case in which fat was found in the fæces; cod-liver oil had been administered in the form

of inunctions, and the child fed alone on Borden's condensed milk.

Dr. Randolph replied that he had found ten per cent. of fat in the fæces of a child which was receiving two inunctions of cod-liver oil daily. He was now conducting some experiments upon this subject, and intended to report the results to the College in a communication to be read at a future day.

— Among the important changes in the tariff on drugs which went into effect July 1st is a reduction on chloroform from one dollar to fifty cents per pound, and an increase on preparations of opium from six dollars to ten dollars per pound.

PEPTONIZED MILK AS A CURATIVE AGENT IN ACUTE DYSPESIA.¹

BY JOHN W. BRANNAN, A. B., M. D., OF COLORADO SPRINGS COLORADO.

PHYSICIANS are often baffled and discouraged in attempting to treat a stomach so disordered as to be absolutely intolerant of all food. The various drugs known as digestives are tried in turn, and the most easily assimilable food is given. Milk in small quantities, either alone or with the addition of limewater, is often well borne, and in such cases a favorable result is merely a question of time. But in other cases the stomach, incapable of performing its functions, demands not simply *digestible* food, but food already *digested*.

Physiology has taught us the nature and workings of the digestive ferments of the body, and physiological chemistry has given us the active principles of those ferments. In selecting a food for artificial digestion we may reasonably choose that one which is most easy of natural digestion, that is, milk. The albumen of meat and eggs can be digested artificially by a solution of pepsine and hydrochloric acid, but the process is of five to eight hours' duration, and the resulting product is far from tempting to a fastidious stomach. Milk, however, by the process I am about to describe, can be digested sufficiently in one hour or even less to be readily taken up by the absorbent vessels of the body. Its taste, when thus prepared, is not at all disagreeable. Moreover, milk contains all the proximate principles necessary to the complete nutrition of the body. Of these principles the sugar, water, and saline matters are already in a state fit for absorption. Milk sugar, though not absolutely identical with grape sugar, is closely allied to it, and, according to Pavy, behaves precisely like it in the alimentary canal. We have left then the casein and butter of the milk, the former to be converted into albuminose or peptone, the latter to be emulsified. The pancreatic juice is the only ferment in the body which combines the properties of changing albuminoids into peptones, starch into sugar, and of emulsifying fats. The extractum pancreatis of Fairchild Brothers and Rogers, of New York, is the preparation I have employed in the following manner: Five grains of extractum pancreatis and twenty grains of bicarbonate of soda are dissolved in four ounces of tepid water. This is added to one pint of fresh milk warmed to the temperature of the body, and the mixture is allowed to digest for about one hour at a temperature of 100° F. The milk when ready should have a slightly bitter taste, or, rather, after-taste. It is now raised to the boiling point, strained, and placed on ice, ready for use. In my experiments I found that the casein of the milk was not completely peptonized, nor the fat entirely emulsified, until the digestion had proceeded for two hours or more. But the milk becomes very bitter and disagreeable to the taste after such prolonged digestion, and in practice one hour's digestion seems to give the best results. As will be seen from the cases detailed below this length of time suffices to render the milk easy of assimilation.

CASE I. E. A., a child of nine years of age, is not very strong, but has a fair digestion, as a rule, though with a tendency to constipation. In consequence of a succession of colds the child's strength became much reduced, and at the time of my first visit subacute,

passing into acute, dyspepsia had developed. The symptoms were nausea and vomiting, and epigastric pain on taking food. After trying a very simple diet and various digestives without good effect peptonized milk was given as the sole food. All dyspeptic symptoms ceased at once, and after two days of this diet other articles of food were, one by one, permitted to be eaten, and were well borne. In five days from the beginning of the attack the child's digestion was apparently perfectly restored, though she had not yet recovered her usual strength. There was marked constipation in this case, which was relieved by Seidlitz powders.

CASE II. is that of Miss B., a young woman of twenty-two, far advanced in consumption. Her digestion has always been rather weak. On the 10th of February, 1883, the patient complained of occasional nausea and vomiting, and also of a troublesome diarrhoea. The vomiting was checked for some time by milk and limewater, and the diarrhoea controlled by lead and opium. On February 23d the vomiting grew much worse, pepsine, lactopeptine, ingluvin, etc., were all tried, but to no purpose. At the same time the diarrhoea became almost uncontrollable, there being six or eight loose dejections daily. The stomach rejected all food, even of the simplest nature. Peptonized milk was now given, and was well borne by the stomach for two days, though the taste of the milk was disagreeable to the patient. There was no diarrhoea during these two days, although no astringent medicines were used. As the patient now began to have a strong repugnance to the peptonized milk it was discontinued, and a return to ordinary food was gradually made. During the month following her digestion remained very good, and but little medicine was required for the bowels. On the 21st of March there was again a little vomiting accompanied with quite severe diarrhoea. Peptonized milk was at once ordered, but mutton and chicken broths were also allowed. The diarrhoea was checked with chalk and laudanum. Again the stomach responded to the milk treatment, though I had but little hope that it would. At the present time the patient's digestion remains fairly good in spite of the steady advance of the disease in her lungs.

CASE III. March 1, 1883, I was called to Mrs. C., a lady two months along in her second pregnancy. Her digestion had never been very strong. She was now suffering from almost constant nausea, which for a time was controlled by lactopeptine and ingluvin and a careful regulation of the diet. After a time these remedies failed of effect, and all kinds of food were vomited, though the patient maintained the recumbent position constantly. Previous to the advent of the nausea the patient had been taking six or seven glasses of ordinary milk daily, but now she could not bear even a very small quantity, having a great distaste to it. Peptonized milk was now given to the exclusion of all other forms of nourishment. The vomiting ceased almost immediately, and after a day or two there was no more nausea. Rest in bed was still maintained for three days; the patient was then able to get up and go about with no further dyspeptic symptoms. After five days of peptonized milk diet rare beefsteak was given once daily, and in a few days more the peptonized milk was given up entirely, the patient longing for plain milk and ordinary food. There has been no return of the dyspepsia, but the patient is, of course, very careful in her diet. She

¹ Read before the El Paso County Medical Society, April 9, 1883.

considers her digestion to be better now than it has been for years.

In this case, as in the first, there was marked constipation. Pills of extract of *nux vomica*, *hyoscyamus*, and compound extract of *colocynth* were employed to combat it.

As bearing upon the question of the rapidity of absorption of peptonized milk it may be well to note one incident in the history of this case. On the first day of the milk treatment the patient had left her bed for some reason twenty minutes after taking a full glass of the prepared milk. The movement was followed by the vomiting of about a tablespoonful of greenish fluid. There was not a trace in it of the milk so recently swallowed. According to the physiologists two hours is the time taken by ordinary milk in digestion.

There are a few points to which I shall refer briefly in closing.

First. It is essential that the physician in charge, or at least some one more intelligent than the ordinary servant, should superintend the first preparation of the milk. In the second case given above the milk was made too bitter on the first day, hence the patient took a distaste to it which she could not afterwards overcome. In the course of the hour taken by its digestion the temperature of the milk may be allowed to rise as high as 115° F. or fall as low as 98° F., but only for a few minutes at a time. It is best to keep it as near to 100° F. as possible.

Second. In the process I have described the pancreatic extract is not the only factor in transforming the casein into albuminose. According to the experiments of T. Schmidt a solution of bicarbonate of soda added to cow's milk diminishes the amount of casein and increases that of the hemialbuminose. Again, the same observer proves that the process of boiling transforms a considerable amount of the casein into hemialbuminose, and thus brings the composition of cow's milk nearer to that of woman's milk. We thus have three forces all tending to make the milk more assimilable for the stomach.

Third. Though I have dwelt especially upon the utility of peptonized milk in acute dyspepsia, I am convinced that it would also be of service in many cases of chronic dyspepsia. The patient in Case III. had been a sufferer from greater or less dyspepsia for years. Less than one week of peptonized milk diet not only relieved all her acute symptoms, but also improved her digestion to such an extent that she can now eat and assimilate all kinds of food.

Fourth. From its readiness of absorption peptonized milk ought to be well fitted for rectal injection. When used for this purpose its digestion might with advantage be carried much further than when prepared for the stomach.

Fifth. The three cases I have reported are all in which I have had an opportunity to try peptonized milk as an easily assimilated food. Though few in number the uniform success of the treatment has led me to publish them with the hope that further trial by other observers may verify the results I obtained.

— An English farmer, aged fifty-nine, of previous good health, was stung in the eyelid by a bee. Signs of collapse appeared at once, and the man died in one half hour after the sting was received.

RECENT PROGRESS IN GYNÆCOLOGY.

BY F. H. DAVENPORT, M. D.

COMPLICATED CASE OF VESICO-VAGINAL FISTULA.

DR. L. A. NEUGEBAUER¹ reports the following interesting case: The patient, a domestic twenty-six years old, was admitted to the Heiligen Geist Hospital in Warschau, for incontinence of urine. Two years before she had borne a child after a labor which had lasted three days after the escape of the liquor amnii, and finally was terminated with forceps. Immediately afterwards urine began to come through the vagina. Six months later she was operated on without success, and a second physician had no better result after trying three operations. The patient therefore entered the hospital.

Dr. Neugebauer found a cicatricial closure of the vagina, one inch above the hymen, which was plainly operative, but not complete, there being two pin-hole openings, one at each corner of the cicatrix. On examining the bladder with the finger, he found the fistula so large, and the edges so rigid, that the only thing that remained was to complete the closure of the vagina. The left hand fistula was successfully closed at the first attempt, and the right hand one at the second, and the patient was discharged well.

Nearly three years later she presented herself again, and reported that for some time she had had pain in the bladder and vagina, and that lately urine had come through the vagina. Examination revealed a small fistula in the middle of the cicatrix. Pressure with the finger showed the presence of a hard body above the septum, and a probe passed through the opening made it clear that it was a calculus. It filled the vaginal canal, and apparently part of the calibre of the bladder, and was immovable. The only feasible course was to open the vagina, extract the stone, and close it again. The septum was divided with the knife, but the opening not being large enough it was still further stretched by compressed sponge. After several days' dilatation, it was possible to seize it with polyp forceps, and with great difficulty to extract it. It measured two and one half inches in length by two in breadth, and two in thickness, and weighed when dried two ounces. It consisted principally of phosphate of lime. Three operations finally reclosed the vagina, and the patient returned home well.

AGE OF MENSTRUATION IN FINLAND.

Dr. G. Heinrichius² has collected from the journals of the Obstetrical Clinic at Helsingfors the following statistics with regard to the first appearance of menstruation in 3500 women, all of the lower classes:—

In 9 women the menses occurred in the 11th year.

² Centralblatt für Gyn., No. 5, 1883.

The average age was $15.82 =$ fifteen years, nine months, and twenty-five days. The population of Finland consists of six sevenths Finns and one seventh Swedes. No difference in regard to the time of the appearance of menstruation between the two races could be discovered.

DRAINAGE OF THE UTERUS (NON-PURPERAL).

Dr. E. Schwarz¹ in considering this subject draws an analogy between suppurating cavities which heal when good drainage is secured, and the hollow organs, such as bladder and uterus, which are the subject of catarrh. The catarrhal affections disappear the more quickly the more freely the secretions can escape. This free drainage has been practically secured in cases of cystitis by making artificial vesico-vaginal fistulæ, or by the long continued use of self-retaining catheters.

In the case of the uterus the drainage is naturally freer than that of the bladder, but through swelling of the mucous membrane, or constriction from flexion, the free exit of the secretions may be hindered. A large quantity cannot collect, as it will be expelled by the contractions of the uterus, but in case of catarrh there is always, according to Schwarz, a small quantity of muco-purulent material, which tends to thicken and become foul. To combat this difficulty the canal has been enlarged, either with the knife or by forcible dilatation, internal treatment has been used to change the chronic into an acute catarrh, and of late years the uterus has been irrigated with disinfecting solutions.

The author describes a method of constant drainage which he has employed with good success. His first attempts were with rubber tubes, but these were either forced out of the uterus or became plugged with mucus, and became a source of irritation. He therefore substituted braids of fine spun-glass, but at first used them too large, so that they caused uterine colic, and irritated the interior of the uterus. By unbraiding and making a small smooth bundle of loose glass fibres, these difficulties were overcome. He used them with the best effect in cases of subinvolution of the uterus. The secretion became somewhat more free, but thinner, and often in a few weeks entirely disappeared, and the uterus became smaller. Also in some cases of mechanical dysmenorrhœa accompanying ante-flexion was the result very satisfactory. He has also used the same method in cases of amenorrhœa. Six cases are briefly given, some where menstruation had never occurred, others where the amenorrhœa was acquired, in all of which the use of the glass drainage was followed by marked improvement.

Schwarz regards this method of treatment as both simple and harmless. Slight uterine colic occurs occasionally, inflammatory reaction never. The glass threads are six to seven centimetres long, tied in a knot at the uterine end, or bent over in the form of a hook, and fastened by a thread. A thread is fastened to the vaginal end so that it can be withdrawn. They are covered with iodoform and introduced with the sound. In cases of endometritis and dysmenorrhœa, they may remain for months, being renewed from time to time as they become foul. In amenorrhœa it is often only necessary to place them for a few days before the expected menstruation. (The reporter fails to see that the value of this method of treatment depends upon the *drainage* of the uterus. The spun-glass merely acts as any slight irritant to the interior of the uterus, and stimulates it,

in one case to involution, in the other to the performance of its natural function, menstruation. The same result is obtained by intra-uterine stema, especially galvanic stem pessaries.)

ÆTIOLOGY AND PROPHYLAXIS OF DISEASES OF THE FEMALE GENITAL ORGANS.

Dr. B. S. Schultze² attributes the apparent greater frequency of such affections in the last ten years to the fact that our growing knowledge leads us to recognize their existence. One of the most frequent and troublesome affections is catarrh of the uterus, with its consequences, pelvic-peritonitis, and cellulitis, retro-flexion and oöphoritis. Its principal cause, aside from masturbation and gonorrhœa, is the entrance of atmospheric air into the genital tract, which occurs even in virgins, the menstrual blood being the channel for the entrance of the infectious material. Therefore the author advises the operative closure of the perinæum when that is torn, and, in the case of multiparæ, the placing at the vulva during menstruation tampons of salicylated cotton to hinder the entrance of air, and the use of warm water injections even during menstruation to remove clots. He warns against vaginal injections in childbed, as favoring the admission of air.

ETIOLOGY OF ENDOMETRITIS FUNGOSA, ESPECIALLY THE CHRONIC HYPERPLASTIC ENDOMETRITIS OF OLSHAUSEN.

Dr. Breuncke³ states that his intention is not so much to add to the pathological and histological knowledge of this affection as to throw some light upon the origin of this form of uterine disease. For a long time all forms of fungous growths associated with metrorrhagia, and sometimes with purulent discharge, were grouped together under the one name, endometritis fungosa. Later Olshausen separated the various forms somewhat, and Bischoff divided them into four anatomically different affections: (1) that form consisting of oedematous normal tissue, and granulation tissue rich in vessels; (2) the decidua form; (3) the diffuse adenoma; and (4) the diffuse sarcoma. Bischoff's third and fourth forms are evidently nothing but the chronic hyperplastic endometritis of Olshausen, divided into these two categories only because in the one case the uterine glands prevail, in the other the intercellular substance, but clinically the same. So Ruge distinguishes a glandular and an interstitial form, and a mixed form between the two. The author accepts the distinction, but claims that it does not depend upon any essential difference in the disease itself, but upon the age of the patient. The older the patient, the more does the glandular form prevail, while with younger persons the intercellular form is most marked. To illustrate this view, and as a groundwork for conclusions as to the ætiology, Breuncke gives the history of six cases. The first and third cases, occurring in women fifty and fifty-one years old, were markedly of the glandular form; the second and fifth, aged thirty-one and forty-three, of the interstitial type. The mixed form occurred in cases four and six, in patients forty-eight and twenty-six years old.

As regards the ætiology, the author first notices as common to all the cases that before the profuse hæmorrhages characteristic of the disease, there were irregularities in the menstruation. From this fact

¹ Centralblatt für Gyn., No. 13, 1883.

² Wiener Med. Blätter, No. 52, 1882.

³ Archiv für Gynäkologie, Band xx., Heft 3.

Beunecke draws the conclusion that the first factor in the case is functional disturbance on the part of the ovaries, characterized by a retardation of ovulation. As a result of such retarded or difficult ovulation, we have congestion of the uterine mucous membrane, not sufficient, however, to cause rupture of the blood-vessels. Such congestion, unrelieved by hæmorrhage, leads to hyperplasia of all the elements constituting the uterine mucous membrane. When the repeated congestions finally lead to rupture of the blood-vessels, we have a mucous membrane which would favor profuse and long-continued hæmorrhage.

This condition of impaired function of the ovary occurs naturally at the climacterium; hence most of these patients are at or past the menopause. It is known that Graafian follicles may ripen after the cessation of menstruation, and it is fair to suppose that the gradual thickening of the albuginea preventing the most of such ripening follicles from bursting the resulting congestion may be only now and then relieved in the way described. A similar effect is produced in younger persons by any weakening influence affecting the general health, or the sexual organs in particular.

As regards prognosis and treatment, the following may be said: The curette must be the chief method of treatment. After this, to restore the lost energy to ovulation, general tonic treatment must be adopted, and in proportion as this is successful will relapses be infrequent. This applies to those cases where the anomalies of menstruation are due to general debility. When, however, physiological or pathological changes of structure in the ovaries are present, the prognosis must be more guarded. In these cases, either all stimulus on the part of the ovary must be prevented or the results of this stimulus, the hyperæmia of the mucous membrane, be neutralized. For this latter purpose the constant use of glycerine tampons is of great service. The author condemns the use of caustics, as it is his opinion that neither is this change in the mucous membrane of a malignant character nor does it tend to become malignant. In accordance with his theory, if a case should threaten to terminate fatally, he would remove the ovaries rather than the uterus.

The author finally says that he by no means considers every case of fungoid growths accompanied by menorrhagia or metrorrhagia as of ovarian origin. They may occur as a result of various local uterine troubles, as chronic catarrh, marked retroflexion, stenosis of the os internum, and small fibroids. As characteristic of the ovarian form are the irregular menopauses which precede the hæmorrhages, the tendency to recurrence, and the greater quantity of fungoid masses brought away by the curette.

The type of fungoid degeneration connected with abortion, the author thinks, is characterized by remains of the decidua vera, and the observations of Küstner and Ruge confirm this view. At the end of the article is a table which shows the anomalies of menstruation before and in consequence of the three following forms of endometritis: (1) endometritis hyperplastica ovarialis; (2) endometritis fungosa or hyperplastica uterina; and (3) endometritis decidualis.

DUCTS OF GAERTNER IN THE FEMALE.

J. Kocks, of Bonn,¹ thinks he has found the remains of the excretory ducts of the Wolffian bodies, which in

the pig and some ruminants persist as the ducts of Gaertner. He has been able to demonstrate two tubules which open near the orifice of the urethra, and run parallel with its course for from five millimetres to two centimetres in length. A sound one millimetre thick easily penetrates. He does not think it possible that they are the openings of glands, as at their end he could, neither with the naked eye nor with the microscope, determine the presence of gland tissue. He concludes that they are the Wolffian ducts, which are the homologue of the ductus ejaculatorius in the male. These open, together with the orifices of the prostate and the utriculus vasculinus, into the urogenital canal, at a point which corresponds to the vestibulum vaginæ in the female. Hence he concludes that the ducts of the Wolffian bodies should open outside of the hymen, and reasoning from the position of the ducts of Gaertner, as found in some lower animals, close to the urethra. The little papillæ on which the openings are often found he compares to the little elevations of the caput gallilaginis where in the male the seminal ducts usually open.

Skene, in the *American Journal of Obstetrics*, for April, 1880, has apparently described the same structures, and calls them glands. He says: "The upper ends of the tubules terminate in a number of divisions which branch off into the muscular walls of the urethra. By injecting the tubule with mercury, and then laying it open, the openings of the branches can be easily seen." Skene says they may be the seat of an inflammation which will give rise to most annoying symptoms, and yield with difficulty to treatment.

TREATMENT OF CARCINOMA OF THE CERVIX.

Dr. Karl Pawlik² has in this monograph thoroughly studied those cases of carcinoma of the cervix which have been operated on in the first gynæcological clinic at Vienna by the galvano-caustic wire. As regards this method of operating the author by no means advocates it as the best. On the contrary he thinks the knife and scissors an equally good method. He has, however, found the results to be so satisfactory with this method that he publishes these statistics with the hope that the publication of large numbers of cases operated on by other methods may lead to a comparison of the *ultimate results*, and some more definite idea of the relative value of the different methods of operating. His main reason for preferring the knife to the galvano-caustic wire is the complex character and expense of the instrument which make it practically useless outside of large institutions. Hæmorrhage, he claims, can be as perfectly controlled by one method as the other. When the disease is high up in the cervix the knife can reach it better, and the author justly says it would be very short-sighted in so grave a disease as carcinoma to depend exclusively on one or the other method. He lays considerable stress upon the value of the slough, and would have cauterization follow the operation with the knife.

The cases cited show that the simple amputation of the cervical disease is followed by better results than the extirpation of the uterus. As it seems probable that in many cases the disease if left to itself spreads into the surrounding cellular tissue rather than upwards into the body of the uterus the extirpation of the whole organ as a prophylactic measure is unnecessary. In deciding which operation is best there is

¹ Archiv für Gyn., Band xx., Heft 3.

² Wiener Klinik, December, 1882.

one point upon which the author justly lays weight, namely, that it does not always follow that because we find thickening in the neighborhood of the uterus and enlarged glands they are necessarily the result of infection. They may be simply the result of irritation, and post-mortem examinations have demonstrated this.

The following are the results of the 136 cases which the writer has collected:—

Ten cases died in the hospital; one almost four months after the operation from recurrence of the disease; one case twenty-five days after the operation from marasmus; eight immediately after the operation; three of anæmia; and five of peritonitis.

Twenty-two cases could not be found; of two, however, it was known that they were in good health two years after the operation.

Sixteen cases left the hospital not cured.

Thirty-one cases died outside the hospital; sixteen of these had in all probability a recurrence of the disease, one after three years; one had a return near the uterus two years after the operation, the cicatrix remaining unaffected; three died of tuberculosis; for the rest the cause of death was unknown.

Twenty-two cases had a recurrence of the affection, but it was not possible to discover when they died. Among them was one who remained in good health for six years, and one for nineteen months. Two had carcinoma outside the uterus, the cicatrix remaining unaffected.

Two died in childbed, without recurrence, one seven and one half years, and the other one year after the operation.

Thirty-three cases were in good health:—

1,	19½ years after the operation.
2,	12 years after the operation.
3,	8 years after the operation.
3,	7 years after the operation.
3,	5 years after the operation.
2,	4 years after the operation.
5,	3 years after the operation.
7,	2 years after the operation.
7,	1 year after the operation.

The author then gives a description of the method of operating and some of the complications. The peritoneal cavity was opened thirty-nine times in the posterior cul-de-sac, and once both in front and behind. Four of these died, two of anæmia, and two of peritonitis.

Hæmorrhage occurred during or immediately after the operation six times; checked five times by iron cotton, and once by the actual cautery. In thirteen cases secondary hæmorrhage occurred; in three vesico-vaginal fistulæ, one of which was due to a rapid recurrence of the growth. In two cases only did parametritis follow.

FIBROMATA AND MYOMATA OF THE VAGINA.

Prof. Ludwig Kleinwächter¹ has collected in this article all the cases of tumors of this character which he could find in the literature. They number fifty, and to these he has added three which he has himself observed. Among the conclusions which he draws from the consideration of these cases the more important are the following: Nothing is known as to their ætiology. In contrast to those of the uterus they may occur in the vagina congenitally, and in earliest childhood, but they are most frequent in the period of sexual activity. The fibromata are the most common,

the myomata the least so, and the mixed forms stand between the two as to frequency. Without exception they occur singly in the vagina. They start from the submucous connective tissue or the muscular layer of the vagina, or the layer of connective tissue between vagina and rectum. Complications with similar growths in other portions of the genital tract are seldom, only three times in the cases cited.

Menstruation seems to be very little influenced, and hæmorrhages are infrequent. Conception occurs in a fair proportion of the cases. It is not clear that pregnancy has any influence on these growths; they may, however, form marked hindrances at the time of labor.

CARCINOMA OF BOTH OVARIES. DOUBLE OVARIOTOMY. RESECTION OF INTESTINE AND BLADDER. RECOVERY.

Dr. Moritz Schustler² reports the following interesting case from Billroth's clinic:—

A married woman who had had six children and one miscarriage had suffered from the following symptoms for four years: intense pain in the hypogastrium at intervals, gradually growing worse, accompanied by fever and tenderness; later shortness of breath and palpitation of the heart, frequent micturition and constipation. A tumor was first noticed five months before the operation, in the left side, the size of an apple, which grew rapidly, so that at the time of the operation it reached almost to the false ribs. Loosely connected with it was a second tumor to the right, and not so large as the first. There was only slight mobility, the surfaces were nodulated, there was no fluctuation. The uterus seemed pushed to the left side and behind. The operation was done without spray, but under strict antiseptic precautions. On reaching the tumor, and attempting to lift it out of the abdomen, it was found to be closely adherent to the upper part of the posterior wall of the bladder. As the tumor seemed to be malignant Professor Billroth decided to excise the adherent portion of the bladder, and a piece three centimetres long and two centimetres broad was removed. The wound was closed by six fine silk sutures. It was then found that the posterior surface of the tumor was so firmly adherent to a part of the small intestine that it could not be dissected off. A piece twelve centimetres long was therefore cut off, and the two ends of the severed intestine joined by fourteen sutures, five internal at the insertion of the mesentery, and nine for the rest of the circumference. The rest of the operation presented no especial difficulties. The convalescence was undisturbed by any complication. Flatus passed on the second day, and on the sixteenth there was an operation of the bowels following an enema. The catheter was used for the first few days only. On the twenty-fourth day the patient left the clinic well. According to later accounts the woman is in perfect health, and fifteen months after the operation there has been no sign of a recurrence. This is said to be the second case of resection of the intestine on record, the first having been performed by Madelung, and described in the *Berliner klinische Wochenschrift*, No. 6, 1881.

MANGANESE IN THE TREATMENT OF AMENORRHEA.

Drs. Sidney Ringer and William Murrell³ call attention to the value of this drug in the treatment of

¹ Zeitschrift für Heilkunde, Band iii., Heft 5 and 6, 1882.

² Wien. Med. Woch., No. 2, 1883.

³ Lancet, January 6, 1883.

certain forms of amenorrhœa. They have tried it for thirteen months, and have notes of sixty-nine cases, both hospital and private. They have used the drug in two forms, the pharmacopœial solution of the permanganate of potash, and the same salt made into pills, principally the latter. The best results have been obtained in young women from eighteen to twenty-five, who, from some trivial cause, such as catching cold or getting wet, have missed a period or two. In some cases the menses were brought on after the amenorrhœa had lasted over a year. Good results, too, were obtained in girls who, from a change of climate, as going from the country to the city, had stopped menstruating. When the menstruation had never appeared the drug was not so certain in its action, but even here it often had a good effect. When the flow was scanty it often markedly increased it. In the case of older women, who, as a result of numerous pregnancies and prolonged nursing, were irregular, the drug acted very well. It had no effect in the amenorrhœa of advanced phthisis, and probably would not produce abortion, but the existence of pregnancy should not be overlooked. If given in the pill form it is best to begin with a grain three times a day, and gradually increase to two grains four times a day. The larger doses have the best results. Usually the effect will be produced in three or four days, but there is no objection to continuing its use much longer. The only unpleasant effect was, in a few cases, a feeling of heartburn or indigestion. It will, of course, have a more decided effect if given for a few days before the sickness is expected.

LACERATION OF THE CERVIX UTERI WITH ESPECIAL REFERENCE TO THE EFFECT ON STERILITY AND LABOR.

Dr. B. F. Baer¹ read a paper on this subject before the Obstetrical Society of Philadelphia. He refers to a paper by Dr. Murphy in the *American Journal of Obstetrics* for January, 1883, in which that author comes to the conclusion that "repair of lacerations of the cervix is usually followed by sterility." Dr. Baer thinks that as far as this statement goes it is true, but that as in the majority of cases of this affection sterility has preceded the repair of the cervix, the more correct conclusion would be that the operation failed to cure it. He gives the result of twenty-seven cases studied with reference to this point. Of this number six were either widows or had reached the menopause, and thirteen of the others had been sterile from five to thirteen years. These last he thinks should not be included, as sterility of so long standing is associated with structural changes, such as connective tissue hyperplasia, which the operation fails to modify. Of the eight remaining cases in which impregnation had occurred within five years previous to the restoration of the cervix four had, to the knowledge of the writer, been safely delivered at full term since the operation. There was no re-laceration in these cases.

In the discussion Dr. A. H. Smith said that a large proportion of the cases operated on by him have become pregnant after operation. He also spoke of the existence of obstinate nausea in pregnancies after operation upon long-standing cases, accompanied with an enlarged and hardened condition of the cervix. He disagreed with the writer as to the effect of the operation on a hyperplastic uterus. He had seen marked

reduction in size follow the repair of the lesion when all other means had failed.

Dr. Goodell said he thought the operation had an influence in causing sterility. Of 169 cases in which he had operated he has known only seven to become pregnant, though he had lost sight of so many that the real proportion could not be known.

Hospital Practice and Clinical Memoranda.

BOSTON CITY HOSPITAL.

SERVICE OF DR. W. C. B. FIFIELD, DR. E. H. BRADFORD SUPPLYING.

REPORTED BY EDWARD J. CUTTER, M. D., LATE HOUSE SURGEON.

COMPOUND FRACTURE OF RADIUS AND ULNA; COMPOUND FRACTURE OF CORONOID PROCESS OF ULNA AND TROCHLEA; SIMPLE FRACTURE OF HUMERUS; SIMPLE FRACTURE OF FEMUR.

JOSEPH G., a printer, twenty-four years old, single, was brought to the hospital on the evening of October 17th. The story was that he had been drinking, and had fallen from the Herald Building to the ground, a distance of about forty feet. He was in a state of shock, not excessive; had evidently been drinking freely.

Dr. Bradford, in charge of the service, was sent for, and an examination under ether showed the following injuries: A fracture of the ulna in the lower fourth, with considerable lateral displacement, communicating with the air by an opening large enough to admit the tip of the little finger. A fracture of the radius at the junction of the middle and upper thirds also communicated with the air. There was more or less comminution, great bruising of the soft parts, swelling and discoloration. There was great swelling around the elbow, with dislocation of the fore-arm backward. There was made out a simple fracture of the humerus at the junction of the upper and middle thirds, transverse, and apparently without comminution. It was noticed at the time that after reducing the dislocated elbow any movement of the fore-arm in extension immediately redislocated it. The opening over the radial fracture was enlarged for the purpose of exploration; the finger passed in found very extensive crushing and laceration, and also a fracture of the coronoid process of the ulna, rupture of the capsule, and "chipping" of the trochlea. Examination of the thigh showed fracture of the femur at the junction of the upper and middle thirds, with considerable displacement.

The question of amputation which came up was settled in the negative for the time being. There was pulsation in the radial artery, and the condition of the patient was such that it seemed likely that he would not survive an amputation at the shoulder. The exploratory incision was enlarged, a counter-incision made over the back of the elbow, clots and blood turned out, the arm washed out with a solution of carbolic acid (one to eighty), drainage tubes put in, with a Lister gauze dressing and an internal angular splint.

The fracture of the femur was treated by Buck's method, using a long T splint instead of sand bags, with weight and pulley, and the foot of the bed raised; coaptation splints applied over the thigh. Heaters to body.

 Repeat pro re nata.

October 28th. Reaction well established. Seen by Dr. W. H. Thorndike with Dr. Bradford. An expectant method of treatment determined on. Great difficulty in preventing dislocation of elbow; a tin internal angular with gutta-percha coaptation splints above and below elbow, over which is the Lister gauze dressing covered with Mackintosh.

October 29th. Considerable febrile action; not much pain; tongue coated; thigh in good position; backward displacement of elbow persists in recurring as there is no point, owing to the bruising, where pressure can be safely applied. The Lister dressing given up, and apparatus arranged for constant irrigation with a solution of carbolic acid (one to eighty).

October 30th, two A. M. Dead.

The point about the case worthy of record is the fracture of the coronoid process without a general smash of the joint. The method of fracture of the coronoid process is a matter of dispute, as in fracture of the patella there are two causes predicated, direct violence and muscular strain. Hamilton regards it as a result of direct violence associated with other fractures about the joint. Malgaigne speaks of it in connection with "luxations" of the ulna. In general works on surgery it is barely mentioned. Dr. Stimson, in his late work on fractures, has collected and reviewed much of the literature on it. On page 428 he refers to the various specimens preserved in museums. It is peculiar that there are so few, and would seem to show that either the accident is very rare or repair very perfect.

It is difficult to see how the accident could happen, in a part so well protected, as a result of direct violence except with a general smash or other fracture of the joint or in connection with a luxation. In the latter case, too, the fact of the brachialis anticus being contracted or not would seem to be an important element, so here muscular strain would have to be considered a cause. Stimson cites the experiments of Lotzbeck, who fixed the elbow semiflexed, and then by striking down on the palm of the hand fractured or tore off the process in five times out of seven. In the case reported it would seem, from the fractures of the fore-arm, the position of the openings, and the comminution, that the man fell on his hand. The fore-arm was pushed with great violence by the lower end of the humerus. The force was so great it seems that the humerus could not resist it, and also broke. If we imagine the arm so far extended as to put the brachialis anticus on the stretch, and yet flexed a little so that the line of force was oblique to the humerus, we have a condition to produce the fracture as found.

The diagnosis here was made out from actually touching the broken bone, but before doing that it was suggested at least by the strong tendency of the dis-

location to recur; and this is put forth by all the writers as a diagnostic point. In a few cases surgeons are reported as having made out the separated fragment in the bend of the elbow.

The strong attachments of the capsule behind, and the broad insertion of the brachialis anticus in front, could prevent any very marked separation, and in this way Stimson accounts for the great chance of perfect repair.

The treatment in an ordinary case is plainly indicated; hold the arm semiflexed; keep the elbow in position; and give it rest. In our accident the fracture of the coronoid proved a most baffling complication at first, as noted; the after-treatment would have in all probability been indicated by his other and graver injuries.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

C. M. JONES, M. D., SECRETARY.

MARCH 19, 1883. DR. C. H. WILLIAMS presided.
 DR. GEORGE STEDMAN read

A CASE OF LAUDANUM POISONING IN AN INFANT ONE DAY OLD. RECOVERY.¹

DR. INCHES asked as to the frequency of convulsions in opium poisoning. He thought it a very unusual symptom, one not laid down in the books, and certainly outside ordinary experience.

DR. STEDMAN could not say how often such symptoms occurred. But in this case, attended with so many convulsions, the evidence was positive that the overdose of laudanum had been given, and it was the only factor at work.

FATAL CASES OF ABORTION.

DR. STEDMAN read a report of Two Cases of Abortion, One presenting Unusual Difficulties in the Post Mortem, the Other in the Ante Mortem, Diagnosis of the Cause of Death.²

DR. GANNETT asked if no pathological or forensic diagnosis was made in the first case. Was not the air in the heart a probable, or at least a possible, cause of death?

DR. STEDMAN replied that no positive diagnosis had been made, and it was the difficulty in diagnosis which gave exceptional interest to the case. It was possible that air had been introduced into the uterine veins while the abortion was performed, and had made its way to the heart without showing itself elsewhere. But he would expect to find evidence of it also in the lungs.

DR. GANNETT thought this very important as a matter of diagnosis. When air is introduced into the veins, we do not always find air embolism of the lungs. Death is caused by the air in the heart paralyzing that organ. The air in the lungs is a far less important factor. A large portion of the lung may be cut off in this way without fatal consequences.

The manner of the death, its suddenness, the absence of other signs, the presence of a certain amount of air in the heart even though not found elsewhere, taken in

¹ See page 52 of this number of the JOURNAL.

² See page 50 of this number of the JOURNAL.

connection with the fact that decomposition had not set in, afford at least presumptive evidence that air was the cause of death.

DR. STEDMAN replied that this view would be reasonable had the death been instantaneous. But the victim lived long enough for the lungs to become cedematous. Such being the case, it was very unlikely that no trace of air should appear somewhere in the lungs as well as in the heart.

DR. WHITNEY said that the first case was interesting on account of the difficulty of establishing a pathological cause of death. The immediate cause of death was suffocation from venous congestion. But we can scarcely believe that this in a healthy girl was the primary condition. It is clearly secondary to some preëxisting cause. At first it seemed as if there might be cerebral disease, and for this reason at the examination the head was opened first. Air might perhaps have been sucked in from opening the large veins of the neck. The air showed itself on the opening of the right ventricle, and the amount of it was very small. It is possible, too, that so small an amount might have entered in the act of opening the heart. No trace of air was found in the lung tissue after very careful examination, and since the patient lived fifteen or twenty minutes, he should have no doubt that it would show itself there in that space of time. There was certainly not air enough to cause any dilatation of the uterine or other veins. Why, then, did she die? For his part he could not say. Something, a finer point than usual, may have been overlooked. Air embolism is the probable cause, but it is not proven.

DR. GANNETT referred to one other point in connection with air embolism, due to air introduced through the veins of the neck or uterus. There has been shown in quite a number of cases a tendency of the air to collect in the right side of the heart and not to pass on to the lungs. The air remains here to be churned over and over again. It is doubtful if the death ought generally to be ascribed to the air embolism of the lungs, for the amount of lung tissue disabled is very small. Yet with solid emboli a large portion may be disabled without any rapidly fatal result. The paralysis of the heart is the real cause of death in these cases.

DR. F. C. SHATTUCK suggested that if the heart's action was already embarrassed by the presence of air, the disability would be materially increased by the cutting off of a relatively smaller aerated space of the lungs, and the fatal result thus hastened.

DR. WHITNEY remarked further, if we accept air embolism as the cause of death, the quantity required was much smaller than he had supposed necessary. There was nothing outside the heart to suggest it. Possibly, too, so small an amount might have come from beginning decomposition of the blood, even though the destructive process had not advanced far enough to be evident.

Dr. Whitney also exhibited photographs of the specimens in this case.

DR. M. H. RICHARDSON also reported several cases of abortion to which he had been called, and remarked that these cases suggested two questions: first, can a woman procure an abortion by the use of a catheter on herself, as was claimed in one case? second, what is the physician's duty, when called to such a case? He had little doubt that the woman operated on herself in the one case, although he thought it must be rare. As

regards the second point, he maintained that whenever called to a case of abortion, a consultation was necessary for self-protection.

DR. C. M. GREEN said it was not difficult for a woman to introduce a catheter into her uterus. The pregnant uterus sinks down nearer the vaginal entrance, and is easily accessible. He had seen several cases in which the patient undoubtedly operated on herself, and he thought it quite frequent.

DR. BUSH and DR. GEORGE STEDMAN reported each a case of

NASAL DIPHTHERIA.

DR. BUSH's case was as follows:—

F. B., of German parentage, aged two years, whose only previous diseases had been feverish exacerbations during the eruption of the teeth, was taken sick the latter part of November, 1882, with a nasal discharge, watery in character, accompanied with elevation of both pulse and temperature.

He was seen by a physician, who diagnosticated "worm fever," and said the child had taken cold.

This train of symptoms continued for two weeks, when the discharge becoming purulent and very offensive, an apothecary was consulted, who said the child was "diseased," and that it had better die.

I saw the patient on December 25th, a month after the commencement of the trouble. There was an offensive discharge of pus, mixed with blood, from the nose. The edges of the nostrils were excoriated, the ulcerations extending to the lips. The nasal mucous membrane was covered posteriorly as far as could be seen, with a grayish deposit, along the edge of which was a distinct red line.

An examination of the pharynx showed the tonsils red and swollen, and though no deposit was seen upon them, the diphtheritic pellicle was found upon the membrane in the naso-pharyngeal space.

There was increased temperature and rapid pulse. The act of breathing was difficult, and was performed with the mouth open. There was diarrhœa, watery in character, and very offensive.

The child would sleep only for a few minutes at a time, waking with a start. There was jactitation, and the head was being thrown constantly from side to side. There were frequent attacks of dyspnœa.

It was with difficulty that the child could be made to take milk or beef tea, though brandy and water was swallowed with avidity. The tincture of the chloride of iron in a mixture of glycerine and water was given as a tonic, and the same was used "topically." The nostrils were washed out with a weak solution of carbolic acid, and iodoform was used for insufflation. An ointment composed of the red oxide of mercury and vaseline was applied to the external parts of the nose, and to the labial excoriations.

The high temperature of the body was reduced by the use of saleratus baths. Stimulants were crowded. The symptoms of impending suffocation which came on at irregular intervals were relieved by the inhalation of steam. This treatment was followed up for a week (six weeks from the date of the invasion of the disease); at the end of which time the mucous membrane seemed free from the deposit. The appetite returned, and he slept well, and apparently was doing nicely, the only thing noticed being that there was regurgitation of food, liquids coming out through the nostrils.

Two weeks later, in the middle of January, the parents noticed that the child could not stand, and I found the muscles of the legs flabby and paralyzed.

The child continued to eat and sleep well. I gave the syrup of the iodide of iron, and ordered that the stimulants, which had been discontinued, should be resumed.

By the 1st of February, use of the muscles of the legs had been regained, but it was noticed that there was difficulty in swallowing, there being a peculiar sound in the throat when this process was attempted, though the patient seemed lively.

On February 3d, the muscles of the head and neck lost their power, the little one crying continually unless the head was held in one position, to wit, with the chin resting on the shoulder of its nurse or mother.

On February 5th it died suddenly.

The treatment during the last week consisted only of food and stimulants.

No autopsy was allowed.

DR. STEDMAN'S case was as follows:—

In July, 1881, I was called to see a child, aged two and a half years, which was said to have a bean lodged in its nose.

It was impossible to thoroughly examine the child until it had been etherized, when a thorough examination was made with the aid of specula and probes. I was unable to discover any foreign body. The child was then taken to the Massachusetts General Hospital, where it was again etherized, and the nasal passages were explored by Dr. R. M. Hodges, who, not being able to find the foreign body, passed a Bellocq's canula, armed as if for plugging the posterior nares; a sponge was attached to the string and was drawn up behind the soft palate and out through the anterior nares; as the sponge was brought forward it brought before it quite a large piece of diphtheritic membrane. The same process was gone through with on the other side of the nose, and with the same result. The appearance of the membrane explained the obstructions to the nasal respiration which had been attributed to the probable presence of a bean.

There were no appearances in the throat or anterior nares which might have led us to suspect diphtheria.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. NANCREDÉ, M. D., RECORDER.

THURSDAY EVENING, June 14th. DR. TYSON, President, in the chair.

KIDNEYS AND HEART FROM A CASE OF CHRONIC BRIGHT'S DISEASE; EXTREME URÆMIC DYSPNOEA; MARKED ŒDEMA; RELIEF TO BOTH BY ACUPUNCTURE; INCIPIENT NEURITIS.

By J. H. MUSSER, M. D.

R. T., aged thirty-five, admitted to University Hospital July 17, 1878. Single; a packer of goods; frequently exposed to draughts while in profuse perspiration; used tobacco to excess; once or twice a year he would spree. At twenty-two he had a chancre(?). No secondary symptoms. Three times he had gonorrhœa. Always healthy prior to present illness; never had rheumatism.

The patient inherited a tendency to phthisis from

both parents, and to rheumatism from his maternal grandmother.

The onset of the present illness was observed two years ago by a sudden night attack of dyspnoea. The dyspnoea continued for nine weeks, worse at night and preventing work in the day-time. Œdema of the feet and frequent micturition accompanied the dyspnoea. He improved, to have a relapse in four weeks of a month's duration, followed again by temporary improvement, and a third relapse. From the latter he never rallied, Œdema, cough, dyspnoea, frequent micturition, and dyspeptic symptoms being constantly present. The cough was dry, and attended by sub-sternal pain. The Œdema was general. When admitted to the hospital, under the care of Professor Pepper, his condition was as above mentioned. During the July, August, and September following the asthmatic attacks continued. In October they were relieved, but the anasarca became more pronounced.

It may not be out of place to say that the dyspnoea was very severe and almost defied treatment. It presented the clinical characters of uræmic asthma, and was relieved only by inhalations of nitrite of amyl or by hypodermatic injections of morphia. The anasarca was very great and not relieved by diuretics, diaphoretics, or cathartics. In October acupuncture was resorted to, with temporary relief to the lower extremities and scrotum;—its good effect lasting five days only, but being so marked as to encourage one in its use. During the following three months the punctures were made about fifteen times, and after each operation about three pints of serum would drain away. The latter part of December erysipelatous inflammation developed about the punctures on the right leg and extended over it. During the progress of the inflammation large bullæ would form, the bursting and continued free discharge of which caused an entire disappearance of the Œdema of both legs. Relief was not only afforded by these operations to the Œdema, but the attacks of asthma notably diminished in frequency and severity. January 8th, two weeks after the inflammation of the right leg developed, sloughing took place. The sloughing was confined to the calf of the leg, was deep, and was attended with free serous discharge from the ulcers. In a few days a low typhoid state set in, he rapidly lost strength, and on the 7th of February died of exhaustion.

When these notes were taken (January 8th) the remaining features of the case were as follows: He was emaciated and anæmic, and his skin was harsh and dry, his countenance anxious. Appetite poor; flatulent dyspepsia marked; the bowels constipated; hæmorrhoids; tympanitic abdomen; slightly enlarged liver; normal spleen.

At the apices of the lungs diminished expansion; flattening, impaired resonance, and increased fremitus at the left; moist crackling and sub-crepitant râles heard throughout the lungs. Apex beat of heart in the sixth interspace one fourth inch inside of nipple line. Veins of right side of neck enlarged. Cardiac impulse moderately strong. At apex a low-pitched systolic murmur; muscular element lessened. At base pulmonary second accentuated. The width of the cardiac area of dullness was increased one half inch to the left and was not changed by full inspiration.

Urine contained albumen; amount varying, at times two thirds, then one third bulk. Hyaline and numerous granular casts.

Ophthalmoscopic examination. Small disks. Myo-

pia. O. D., disk dirty gray, veins tortuous. No marked change in the color of the nerve; outlines misty and it slightly swollen. O. S., disk same but more marked. No hæmorrhage, in either eye. Diagnosed incipient neuritis.

Autopsy five hours after death. No rigor mortis; emaciated; commencing ecchymoses. Great fullness of the venous circulation.

Lungs. Apices bound down by adhesions. Slight right hydrothorax. Base of left lung, ante and post, adherent. At left apex three or four areas of catarrhal pneumonia.

Heart. Weight twenty-one ounces; left ventricle, wall hypertrophied; mitral valve insufficient, admitting almost three fingers; its cusps thickened; one leaflet of the aortic valve slightly diseased; left cavities increased in size. Aorta atheromatous, a large patch especially one half inch from the valves.

Liver enlarged, hard, congested. Kidneys small, congested, capsules adherent; relation of cortical to medullary substance normal.

Microscopical examination of kidney showed decided interstitial nephritis with fatty degeneration of the tubular epithelium. Liver slightly cirrhotic and fatty. Muscular fibres of the heart slightly undergone fatty degeneration.

AORTIC VALVE DISEASE DUE TO THE COMBINED ACTION OF STRAIN AND RHEUMATISM; EXCESSIVE DILATED HYPERTROPHY.

By J. H. MUSSER, M. D.

Neither the habits, the hygienic surroundings, nor the social conditions of Mr. C. K., from whom these specimens were removed, had any relation to the cause of his illness. As a laborer in a rolling mill his occupation might have had some predisposing influence on the localization of the disease, he being exposed to extremes of heat, and obliged to do heavy lifting. The family history did not disclose hereditary disease. Withal in the past twenty years—at this noting he was aged forty-seven—he had had frequent attacks of inflammatory rheumatism, and in 1875, four years previous to this account, he had an unusually severe attack of palpitation and of indigestion, characterized by pain and vomiting. These symptoms increased in frequency and severity, and were often attended by œdema of the legs. The last three years he was unable to work. Within the year he lost in flesh and strength, and had several attacks of pulmonary congestion.

I abstract the condition on admission to the hospital, December, 1879, from notes taken as registered:—

“Slightly emaciated; sallow complexion; anæmic appearance; countenance of suffering; dry skin; cold extremities; ankles œdematous; muscular weakness; tremor on exertion. Marked prominence of lower part of chest and bulging of præcordia; sternum pushed forward, lower half especially, giving pouter-pigeon appearance. Impulse marked in normal cardiac area, and extending two inches to the left; epigastric pulsation; pulsation of veins of neck; apex beat in sixth interspace one inch outside of nipple line. No hepatic pulsation. A line drawn diagonally from the second right costo-sternal articulation to the fourth rib, one inch from right nipple line, and then vertically to the hepatic dullness, represents the right border of cardiac dullness. From the top of the third left rib, one inch from the sternum, a uniformly curved line, ex-

tending to the apex beat, showed the left limit. By joining these lines with horizontal ones the upper and lower borders are defined.

“On auscultation at the aortic orifice a strong systolic murmur, transmitted to the vessels of the neck, and a rough diastolic murmur, transmitted to the base and along the sternum, is noted. At the xiphoid cartilage and at the apex systolic murmurs, differing in pitch, are heard, the latter also at the spine of the left scapula. Pulse small, feeble, compressible; not counted.

“Cough, muco-purulent expectoration are complained of, and the physical signs of bronchial congestion are observed. The appetite is poor; pyrosis and flatulence distressing; bowels constipated. Urine slightly albuminous, no casts.”

Subsequent course. With calomel and soda and a liquid diet at first, followed by digitalis and quinia, the venous stases had disappeared, and the cardiac symptoms ameliorated within a month. After exposure to cold internal venous congestions and œdema had supervened, and in five days, January 20, 1879, he died of pulmonary congestion.

At the autopsy the lungs, liver, spleen, and kidneys were found characteristic of dilatation of the heart, congested, and with increase of connective tissue in the latter three organs. The heart presented very interesting lesions. It was enormously enlarged, weighing thirty-two ounces. The right heart was dilated. The ventricle wall averaged one eighth inch in thickness. The tricuspid orifice was insufficient, and admitted four fingers. The left ventricle wall averaged one half inch in thickness. The mitral valves were slightly thickened, and a few opaque patches were seen. The aortic valves presented a remarkable appearance. Two of them were fused together, and were rigid, projecting in the lumen of the orifice, the other valve also assisting in narrowing the calibre of the opening by rigidly jutting outwards. The lumen was scarcely more than a slit. The coronary arteries were not closed, and were found at the bottom of pouches with calcareous walls. On one side the deposited calcareous matter of which the valves were composed extended under the endocardium to the base of one of the mitral leaflets. Of course the valves were covered by endothelium.

It is of interest to note that the mitral valves comparatively escaped the inflammatory storms while the aortic valves were so markedly affected, contrary to the usual rule. It is suggested that a chronic valvulitis, or at least hyperæmia, might have been started by the strain incident to his occupation, and hence the valves readily invited acute inflammatory processes, the present condition being a secondary degenerative result thereof.

TUMOR OF THE SCIATIC NERVE.

Presented by DR. G. DE SCHWEINITZ.

The following case occurred in the hospital practice of Prof. John Ashhurst, Jr., and it is by his permission that I exhibit the specimen. The patient from whom this tumor was taken is at present an inmate of the University Hospital, and gives the following history:—

On June 16, 1864, owing to a gun-shot wound of the right thigh, he sustained an amputation of that member at the junction of the middle with its lower third. The flaps sloughed, and a few weeks later a reamputation became necessary. This stump healed, but was somewhat conical in shape, and never, from the very beginning, comfortable, being subject to fre-

quent attacks of severe neuralgic pain. Within a year from the date of the amputation a small lump, tender to the touch, was noted, situated posteriorly and a little to the outer side of the stump. The pains now became more severe and more frequent, and were of a "jumping" character, to use the patient's own language. The tumor increased slowly in size until three years ago, when its growth became more rapid, and at the same time the painful nature of the affection more pronounced, until lately the suffering was well nigh unbearable. Finally the growth assumed the size which you see it now presents, and on the 12th of last month Dr. Ashhurst removed it, since which time the patient has been free from all pain except such which naturally accompanied the healing of his wound.

The growth is an irregularly-shaped mass, about as large as a small hen's egg, having an external envelope of adipose tissue, loosely held together by connective tissue. On section the interior is seen to be a somewhat elastic, rather dense-looking growth of whitish color, over which pass a few yellowish fibres, probably strands of the sciatic nerve.

Microscopic examination of the true tumor mass shows an entire absence of any nervous elements, a section exhibiting fat cells, fibrous tissue, some spindle cells, and numerous free nuclei near the enlarged and dilated blood-vessels.

The tumor would, of course, be classed clinically as a neuroma following amputation, while in truth its pathological nature is that of a fibroma. It is interesting that a growth causing so much pain should be without any demonstrable nervous endowment, and surgically it is further worthy of note because its removal was attended with immediate and probably permanent relief to the patient, a desired result which is by no means always obtained by the excision of these growths.

BACILLUS TUBERCULOSIS.

DR. LAURISON, by invitation, made some remarks upon the bacillus tuberculosis, and exhibited a number of specimens. He said that he did not employ nitric acid in preparing his specimens, as it seemed in many cases to bleach out all the bacilli from the tissues, but formic acid in the proportion formic acid one pint, alcohol two pints. It was a curious fact that the bacilli occurred in patches while in other parts apparently equally diseased they were present in small numbers.

Recent Literature.

The Principles and Practice of Medical Jurisprudence.

By the late ALFRED SWAINE TAYLOR, M. D., F. R. S. Third Edition, edited by THOMAS STEVENSON, M. D., F. R. C. P., Lecturer on Medical Jurisprudence at Guy's Hospital. Two Volumes. Philadelphia: Henry C. Lea's Son & Co. 1883.

When a work so well known and of such acknowledged excellence as Taylor's Medical Jurisprudence appears in the book-stores in a new edition it is scarcely necessary that the JOURNAL should do more than to announce the fact as evidence at once of the high esteem in which these volumes are held and of the steadily growing interest which the subject of which they treat is developing. Any elaborate analysis or review of these writings is certainly superfluous, for they long ago took a leading place as a standard English treatise on forensic medicine, and they may well

be indifferent alike to the praise and the disparagement of a new generation of critics. The lamented death of Dr. Taylor has necessitated that the task of revising the text for this latest edition should pass into new hands, and the title-page accordingly bears a second and comparatively unfamiliar name in conjunction with that of the honored professor at Guy's; but Dr. Stevenson, the new editor, was well equipped by his fourteen years of experience as the colleague of Dr. Taylor at Guy's, and by his succession to the chair of his senior as a lecturer on medical jurisprudence, to do full justice to his work, making it, as he says in his preface, a "labor of love." Without doing harmful violence to the original composition he has pruned away much that was superfluous, and thus made room for such additions as the constant progress in medico-legal science rendered necessary; all authors, for example, whom Dr. Taylor quoted with full recognition of their identity have been shorn of their titles and reduced to a uniform rank; "Dr. Bennett Dowler, of New Orleans," is credited in the edition of 1873 with some observations on "post-mortem calorificity;" it is plain "Dowler" who is quoted in the same connection in 1883.

The additions to the text consist largely of illustrative medico-legal cases which have been reported in the last decade; these have taken their permanent place in their appropriate relations, and have materially increased the value of the treatise as a work of reference. Most of these cases are naturally drawn from British sources; we cannot forbear the regret that the editor has utilized so sparingly the medico-legal experience of countries other than his own.

In the section on toxicology considerable new matter is introduced, comprising the full discussion of comparatively new agents like osmium, gelsemium, carbolic acid, chloral, carbon, disulphide, etc., while new chemical processes for the identification of the older poisons are described with sufficient fullness.

Our local pride is gratified by a paragraph in the chapter on coroners' inquests. Dr. Taylor's vigorous denunciation of the English coroner system has been supplemented in the new edition by a brief statement of the methods employed in Scotland, France, and Germany for the investigation of violent deaths. To this is added the following: "A very satisfactory system of holding inquests has been adopted by the State of Massachusetts, and is said to work well. Coroners and juries are wholly dispensed with on the preliminary examination. A competent medical man is duly appointed, in consequence of his fitness, to the post of district medical officer. He inspects the corpse; and if, on such examination, he thinks further examination necessary he is required by the district attorney to make a post-mortem examination in the presence of two witnesses, and makes his report. If it is to the effect that death resulted from violence the case is then investigated by the local public prosecutor. The medical officer is empowered to call in the aid of the chemist. To guard against negligence and fraud, if the examiner report that the death was not caused by violence, and the legal authorities be of a contrary opinion, they cause an inquest to be held in a prescribed manner." The *modus operandi* of the medical examiner law might have been stated differently and more accurately by one more familiar with its practical details; but that the general merits of the system have obtained this cordial trans-Atlantic recognition is a fact worthy of mention.

Medical and Surgical Journal.

THURSDAY, JULY 19, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,

NO. 4 PARK STREET, BOSTON, MASS.

THE MEDICAL DEPARTMENT OF THE BRITISH ARMY IN THE EGYPTIAN EXPEDITION.

THE British journals, professional and non-professional, have lately contained many references to the medical affairs of the recent Egyptian campaign, called forth by the report of a committee appointed by the secretary of state for war to examine into the organization of the Army Hospital Corps, Hospital Management and Nursing in the Field, and the Sea Transport of Sick and Wounded. The committee naturally studied the organization as exemplified by its workings in Egypt, and notwithstanding the express declaration in the report that it was not intended as an investigating committee the testimony which has attracted most attention is that relating to the Egyptian war.

The medical history of our own war is not so far behind as to be forgotten, especially when kept alive as it has been by the memorial volumes of the War Department; and the investigation of the Medical Department of the British army has a very different interest to Americans to-day than it would have had before our own war.

The committee, which is known by the name of its chairman, Lord Morley, examined a large number of witnesses, from his royal highness the Duke of Cambridge, commander-in-chief, down through all grades and branches of the service, and the evidence and report makes a ponderous blue-book of 771 folio pages, which lies before us. None of the complaints seem to be against the surgeons personally, but rather to be directed against the "system." The medical history of the campaign is exceedingly interesting. The testimony shows plainly how differently different individuals look upon the same matters, and how impossible it is for a single individual to see the whole of military affairs that are going on under his own eye.

Perhaps the best means of gaining a fair knowledge of the campaign from a medical stand-point will be to confine our attention chiefly to the hospital at Ismailia, where the difficulties seem to have been greatest, and where the complaints were, perhaps, more numerous than elsewhere, and to the battle-field of Tel el Kebir. These will illustrate two different phases of the service, and show, perhaps, the weakest and strongest points in the medical management.

The campaign was a short and brilliant one. It was an advance from on ship-board into a hostile country, where a base had to be seized, and where, without an opportunity for preparation, the medical

staff had sick waiting for care the day of landing, and wounded the day after. The first troops were landed at Ismailia on August 21st and 22d, and were immediately sent forward. On the 22d the Khedive's palace was handed over to the Medical Department, and was temporarily occupied by a portion of a movable field hospital.

A movable field hospital is a hospital equipped in the lightest manner for moving with the troops. It is not provided with many things absolutely essential in a stationary hospital, for facility of transport is a chief consideration. It has no bedsteads, but is provided with paillasse cases which are filled with straw and used as beds; and in Egypt stretchers on short legs were used as bedsteads for the most serious cases.

On the 23d the remainder of the field hospital was landed, and joined the first part at the palace, which was a large building, entirely empty, and wanting in many sanitary requirements.

On the 27th two stationary hospitals were landed and relieved the field hospital at the palace. This necessary change could not fail to cause inconvenience in the hospital administration.

The field hospital on being relieved at Ismailia took its belongings to the front. The men of the hospital corps were many of them new to their duties; they were not only without proper training, but they were obliged to transport the hospital material to the palace, all other help being employed in the landing and movements of the fighting portion of the army, and were constantly called on at all hours of the night to form stretcher parties for the moving of sick and wounded.

At this hospital 767 cases were admitted from the 23d to the 31st of August, and 1311 from September 1st to September 15th. As many as 350 were brought in at one time. After the battle of Tel el Kebir 194 arrived after midnight, two hours before a telegram intended to prepare for their reception (in the hospital having the largest casualty practice in London the number daily admitted is under twenty), all of which entailed a vast amount of labor not only in their reception but in their subsequent removal to transports for return home to leave room for further arrivals from the front. Some of these patients were very sick, and some badly wounded, but at this particular hospital the mortality was only at the rate of 0.5 per cent.

This hospital was administered as a non-dieted hospital, in which the daily ration of a healthy soldier is drawn for each patient, and all patients coming from their regiments are supposed to bring their ration for the day with them, and no separate arrangement is made for sick and wounded officers. The difficulties inseparable from this arrangement were avoided as far as possible by the free use of extra medical comforts, so that every patient on entrance was supplied with beef tea, etc.

During the first week the difficulties experienced were very great, but notwithstanding the great strain upon the hospital corps necessary to the establishment of the hospital it does not appear that anything abso-

lutely necessary for the treatment of patients was wanting. From the first landing military necessity required the most rapid advance. The difficulties of the landing were very great, and in consequence the troops suffered for want of food and ammunition, and medical stores came to hand but slowly. The surgeon-general seems not to have been in the confidence of the general commanding, and did not know that Ismailia was to be considered the base. The original plan was to make Cyprus the medical base on which the hospitals at the front should be evacuated, and to use in Egypt chiefly the hospital ships. A sudden change from this plan was also a cause of delay in properly supplying the hospitals.

During the whole occupation of the Khedive's palace there was no outbreak of erysipelas, hospital gangrene, or pyæmia; a similar freedom from epidemics existed at all other hospitals.

Of the surgical arrangements at the battle of Tel el Kebir we can give but the merest sketch. The stores and equipments of a field hospital were sent up the canal to the nearest spot and a field hospital established there at the very edge of the battle-field. At this spot the arrangements were complete for any attendance that could possibly be required. The boats were immediately prepared for the transportation of the wounded. The bearer companies accompanied the troops and established dressing stations at more advanced positions. In taking the wounded to the hospital they were brought so far on their way to the point in the rear to which they must eventually go. The men were then placed upon the canal boats and drawn by mules or horses to Kassassin and Ismailia. Many of them remained on board these boats until embarked on the Carthage, having water transport direct from battle-field to the hospital ship.

Of the care of the wounded at this battle General Wolseley remarked, "They were moved with very great comfort to the men themselves. I never saw wounded men better cared for than they were."

Attention was drawn to the medical conduct of the campaign chiefly by letters from various war correspondents, who seem to have picked up and repeated much idle gossip without taking pains to verify it. Of the complaints of the correspondents many were vague and impossible to trace. Only where particular instances were given was it possible to ascertain the truth or falsity of the reports. In one particular case it was stated that the arm of a certain trooper, who was named, was amputated at the shoulder-joint without an anæsthetic, a general deficiency of medicines being alleged. In this particular case it was shown that chloroform was used during operation and also at a previous examination. It was charged that one officer dosed his patients indiscriminately with the same pill taken from the same box. The box referred to was part of the regular field equipment divided into several compartments, each containing different drugs. Some of the complaints of the sick themselves sound very familiar to civilian ears, for instance, those of the men with digestive troubles who were kept on liquid diet, and "had nothing to eat;"

that of the officer with a wound which it was feared had entered the knee-joint who prescribed brandy for himself, and was denied the privilege.

What was probably the first of the series of letters throwing discredit on the medical management was based on the complaints of one of the remaining regimental surgeons of the household troops. While on the transport he complained of the want, among the drugs furnished him for use on ship board, of flaxseed meal, tincture of arnica, lead lotion, and tow, though the first was found among the ship's stores, and he had the acetate of lead. It would seem that the doctor expressed himself more warmly, than the actual condition of affairs would warrant, to the correspondent of the *Times*, and was surprised and shocked to see his complaints given the publicity of that widely circulated newspaper.

We have thus far tried to give in the briefest manner some of the leading features of the campaign, and a portion of the circumstances that led the public to feel that the medical conduct of the campaign was faulty. Next week we shall give an account of the evidence before the committee, more particularly that of General Wolseley.

AN AMENDMENT TO THE MASSACHUSETTS ACT TO PREVENT THE ADULTERATION OF FOOD AND DRUGS.

THE Massachusetts Legislature of last year enacted a law with similar provisions to those of New York and New Jersey, relating to the prevention of adulteration of food and drugs. The execution of the law was intrusted to the State Board of Health, Lunacy, and Charity, and the sum of \$3000 was appropriated to carry on the work. The Board appointed two competent analysts, who have done efficient service, at least five hundred samples having been analyzed by them since September last. By no means the least important work has been the inspection and analysis of the milk supply. During the past two months 88 samples of milk, chiefly from Boston, have been analyzed, of which number only ten, or less than 12 per cent. of the whole, proved to be above the standard required by the public statutes (thirteen per cent. of solids). The greater number were largely adulterated or *extended* with water. This is a widely different result from that obtained by the milk inspector of Boston.

Believing that more efficient means could be furnished for preventing this iniquitous work, certain members of the Legislature, especially from the agricultural districts, presented a bill early in the winter, amending the act of last year with reference to the milk supply. But certain unscrupulous manufacturers of adulterated food had so tinkered the bill in their own interests that its original meaning was entirely altered. Fortunately this bill, after passing the House, was defeated at its final stage in the Senate.

A new bill was then introduced, relating to the adulteration of milk, by the provisions of which \$2000 are added to the original appropriation, making a total

of \$5000 to be expended for the prevention of food and drug adulteration. It also provides that an account of the prosecutions under the act, as well as an itemized account of expenditures, shall be annually reported to the Legislature.

Singularly enough no allusion whatever is contained in the amendment to the subject of milk. As the evident intention of the framers of the bill, however, was to make special provision for this important matter, we have no doubt that their wishes will be fulfilled.

As affecting the infant life of our large cities, there is nothing more desirable than a pure and undiluted milk supply.

MEDICAL NOTES.

—A contemporary proposes to get rid of the use of "spoonfuls" as doses by the following expedient: Let each bottle (vial) be provided with a strip of paper pasted on, which strip is accurately divided with as many lines (marks) as the bottle contains doses to be taken, the lines to be numbered, beginning with the topmost, and let the direction read: Take one eighth (fourth, twelfth, etc.) part, etc., as the direction shall run, or, perhaps better, take one division, etc. The strip to reach from the bottom of the bottle (vial) to the top of the liquid, not farther.

—Dr. J. M. Toner, of Washington, has published a list, compiled in part from the returns of the census of 1880, of persons over seventy-five years of age, who were residing in the District of Columbia at the time the enumeration was made, June 1, 1880. The list contains the names of 1652 persons of seventy-five years of age and over out of a total population of 177,624. This number, on analysis, shows that there were 1007 whites — males 398, females 609; blacks, 539 — males 164, females 375; and mulattos 106 — males 26, females 80. It will be noticed that the predominance of the females is quite marked. Of the white males 282 were between 75 and 80 years of age, 118 between 80 and 90 years of age, and eight between 90 and 100 years of age. Of the white females 341 were between 75 and 80 years of age, 239 between 80 and 90 years of age, 27 between 90 and 100, and two over 100 years of age. Of the black males 79 were between 75 and 80 years of age, 69 between 80 and 90, 14 between 90 and 100, and two over 100 years of age. Of the black females 169 were between 75 and 80 years of age, 59 between 80 and 90, 36 between 90 and 100, and 11 over 100 years of age. Of the mulatto males 11 were between 75 and 80 years of age, 13 between 80 and 90, and two between 90 and 100. Of the mulatto females 35 were between 75 and 80 years of age, 36 between 80 and 90, four between 90 and 100, and five over 100 years of age.

—The Legislature of Connecticut has passed a law requiring that coroners in that State shall hereafter be attorneys at law, familiar with criminal practice and medical jurisprudence, and that one such person for each county shall be recommended by the State's attorney for such county to, and be appointed by, the judges of the superior court to hold his office for the

term of three years, and until another shall be duly appointed in his stead, unless sooner removed from office for cause. And the said coroner is required to appoint for each town of the county "an able and discreet person, learned in medical science, to be medical examiner." Upon these officers is devolved all the duties in detail which have hitherto *not* been exercised by coroners under the old régime, and such as are common throughout the United States outside of this commonwealth.

—A Canadian contemporary gives the following as a verbatim copy of a prescription actually dispensed by a druggist of the Lower Provinces from one of the most eminent practitioners of that vicinity. The disease of the patient is not stated, but we can recall no malady that it might not have been unless it were ingrowing toe-nail:—

"Ry Pot. Bromide, Pot. Chlor., Pot. Iodid., Pot. Acetas, Pot. Bi-Carb., Ammonia Chl., Ammonia Bromide, Ext. Calombo, Ext. Gentian, Ext. Taraxaci, Ferri Pyrophosphas, aa 3 ij.; Syrup Ferri Iodide, Tinct. Valerianas Amm., Dil. Phosphoric Acid, aa fl. oz. i.; Pepsine, gr. xxx.; Tinct. Cannabis Indica, Tinct. Digitalis, aa fl. oz. ss.; Syrup Calcii Lacto Phosphas, Glycerine, Syrup Tolu., Tinct. Cinchona co., aa fl. oz. ij.; Liq. Arsenicalis, fl. dr. ss.; Tinct. Arnica, fl. dr. ss.; Ext. Nux Vomica, gr. x.; Ext. Conii, Ext. Belladonna, Ext. Hyoscyami, gr. vi.; Chloroformi, gtt. x.; Quinine, 3i.; Alcoholis, q. s., fl. oz. xvi. M. Sig. Shake and take two teaspoonsful after each meal three times a day in a glass of milk."

NEW YORK.

—During the week ending at noon July 8th, which included the recent period of extreme high temperature, no less than 1051 deaths were reported in the city; the largest mortality of the year thus far. Of the deaths, 672 were of children under five years of age, and of these 377 died of diarrhoeal diseases. Eight persons died from sunstroke. The greatest mortality was during the last twenty-four hours, when 214 deaths were recorded at the bureau of vital statistics. Of these 125 were of children under five years of age, 97 of whom died from diarrhoeal diseases. Among the deaths from cholera infantum were those of three triplets who were born on the 9th of November last; all three children being carried off within forty-eight hours.

—The new Croton Aqueduct Commissioners have organized, and elected Mayor Edson president of their body. At the meeting when this took place a series of rules and regulations for the government of the commission were adopted, various standing committees were appointed, and it was determined that stated meetings should be held every Wednesday, commencing with the 1st of August. At a recent meeting of the Board of Health Prof. Elwyn Waller, chemist of the department, reported that he had made a careful examination and analysis of the Croton water, in accordance with a request of the Board, and had found the purity of the water entirely unimpaired, while there was at present no perceptible odor about it.

—A Harlem druggist who is charged with having caused the death of a man who applied to him for medicine for the relief of diarrhoea by giving him a mixture containing opium in fatal quantity, has also been arraigned in the Jefferson Market Police Court on the charge, preferred by the Medical Society of the

County of New York, through its president, Dr. David Webster, of practicing medicine without a diploma. He pleaded not guilty, waived examination, and was admitted to bail.

Correspondence.

MEDICAL EXPERT TESTIMONY IN THE CHICAGO LARD INVESTIGATION.

CHICAGO, July, 1883.

MR. EDITOR, — The lard investigation, now in progress before the Directors of the Chicago Board of Trade, has been the occasion of the demonstration of many interesting facts in chemistry and microscopy.

For the benefit of those who do not read Chicago papers, the facts in the case will be very briefly sketched: A lard speculator, Mr. Peter McGeoch, engaged to buy of Messrs. Fowler Brothers 500,000 tierces of prime steam lard. Prime steam lard is the technical term for pure hog fat. When the lard was ready for delivery Mr. McGeoch refused to accept it, on the ground that it was adulterated, and brought the matter before the Directors of the Chicago Board of Trade, seeking damages for the violation of the contract by Messrs. Fowler Brothers. These facts transpired six weeks ago, and since that time the Directors of the Board of Trade, about fifteen in number, have been weighing the merits of the case, in *secret* session, although the public has experienced no difficulty in obtaining all the news.

Mr. Delafontaine, chemist for the prosecution, testified that he had detected in Fowler Brothers' prime steam lard two adulterations, (1) tallow, (2) cotton-seed oil. The test employed for the detection of tallow is known as the stearine test, and depends upon the assertion that tallow contains more stearine than lard. As manipulated by Mr. Delafontaine, a portion of the suspected lard was treated with nine to ten volumes of a solution of equal parts sulphuric ether and alcohol; the mixture was well shaken up and allowed to stand for twenty-four hours, when the stearin (?) had crystallized out, the supernatant fluid was decanted, the residuum washed with ether and alcohol, filtered, dried, and weighed. Pure lard, according to Mr. Delafontaine, contains one per cent. stearine, while tallow contains a much higher percentage. The suspected specimens which were examined contained three to five per cent. stearine, and Mr. Delafontaine drew the conclusion that the lard was adulterated with tallow.

Professors Remsen, Doremus, Witthaus, Sharples, Habershaw, and Haines, chemists for the defense, have demonstrated the unreliability of the stearine test.

The average quantity of stearine in lard and tallow has been found to be indeterminable. Professors Remsen and Haines, in examining different specimens of pure lard, obtained results varying as much as 800 per cent.

Mr. Delafontaine's standard for stearine in lard was found to be entirely too low. It was conclusively shown that lard always contains at least three to five per cent. stearine, and very frequently exceeds these limits. The chemists for the defense found that the lard of Messrs. Fowler Brothers contained three to five per cent. stearine. They demonstrated that a mixture of lard and tallow, according to the stearine test, yielded less stearine than pure lard.

Professor Allen, of England, made the statement, some years ago, that it is impossible to determine, by a chemical analysis, whether a given fat comes from a hog or a beef, and the chemists for the defense have indorsed this opinion.

Mr. Delafontaine testified to the presence of the second alleged adulteration, cotton-seed oil, upon the evidence furnished by the elaidin test. This test depends upon the fact that when olein is acted upon by nitrogen peroxide (N_2O_2) it is converted into a solid mass, termed elaidin. Non-drying oils, of which olive oil is typical, when acted upon by nitrogen peroxide, are converted into elaidin; drying oils, of which linseed oil is typical, when acted upon by nitrogen peroxide, are affected very slightly; cotton-seed oil, occupying a middle position in its chemical relations, is affected to an intermediate degree.

The chemist for the prosecution treated a portion of the suspected lard with absolute alcohol, which dissolves out the olein, but has little action upon palmitin and stearine; the supernatant fluid was decanted, evaporated down, and treated with nitrogen peroxide. The fluid became only *partially* solid, and the presence of cotton-seed oil was regarded as demonstrated.

The chemists for the defense demonstrated the fallacy of the elaidin test in a convincing manner. Two specimens, one of pure lard, the other pure lard with an addition of ten per cent. cotton-seed oil, by weight, were treated according to the method of the elaidin test. The mixture of lard and cotton-seed oil solidified more rapidly than the pure lard. Three specimens of the suspected lard and one specimen of pure lard solidified with the same degree of rapidity. Further, the absence of cotton-seed oil was absolutely demonstrated by a number of tests, of which some of the most important were the sulphuric and nitric acid color tests of Professor Sharples. These color tests do not depend, as has been asserted, upon impurities present in the oil, but are perfectly characteristic with bleached oils or cotton-seed stearine.

The microscopical evidence, adduced by Mr. Hirsch for the prosecution, as to the presence of cotton-seed oil, was of a trivial character and damaging to whatever reputation he may possess. Mr. Hirsch testified that he had detected, by the aid of a magnifying glass, a cotton fibre in the lard of Messrs. Fowler Brothers, and inferred from this discovery the presence of cotton-seed oil as an adulteration.

The palpable absurdity of Mr. Hirsch's testimony was made manifest by the defense upon the ground (1) that it required for the accurate recognition of a cotton fibre a magnifying power of at least fifty to sixty D., while the glass of Mr. Hirsch had a power of six to eight D.; (2) that cotton fibres were constantly floating in the air, and their presence in the lard was accidental.

Dr. W. T. Belfield, Director of the Microscopical Laboratory in Rush Medical College, was retained for the defense at the suggestion of Professor Haines, upon 12th June, and he has since furnished, by means of his microscope, the clearest and most convincing evidence for the defense.

Dr. Belfield showed that by dissolving fats in ether and allowing them to crystallize out, crystals characteristic of lard and tallow may be readily obtained. The crystals from an ethereal solution of lard are rhomboidal plates with beveled edges, while those from an ethereal solution of tallow are plume-shaped, curved into

the form of an italic *f*. Dr. Belfield takes ten grains lard and dissolves it in two fluid drachms Squibbs' ether, and allows the solution to stand twenty-four hours, until the ether has evaporated and the crystallization is completed. The crystals are mounted in alcohol for examination, or may be secured after the dry method. The chemical constitution of these crystals has not been ascertained as yet, and no theory as to their chemical nature is advanced.

Twelve lettered specimens of lard were submitted to Dr. Belfield for examination by Dr. Tilly, who kept a careful record of the letters. The results of Dr. Belfield's examination coincided exactly with Dr. Tilly's list. Three of the specimens, pronounced by Dr. Belfield to be free from tallow crystals, were taken from the suspected Fowler lard.

Dr. Belfield has prepared micro-photographs of the lard and tallow crystals, as well from pure as adulterated specimens, and has presented them for inspection to the Directors of the Board of Trade. He states that the characteristic crystals of tallow can be certainly discovered when the admixture of the fat with lard amounts to five per cent. by weight; that he has reason to believe that even smaller admixtures — say two to three per cent. — can be detected with equal certainty, although he has not had time to establish this latter point beyond possibility of doubt. In the few weeks that have elapsed since the trial began no time, sufficient for an exhaustive study of these crystals, has been found, but Professor Remson calls these micro-photographs "marvelous proofs" of the purity of the submitted lard.

LETTER FROM NEWPORT.

MEETING OF THE SUPERINTENDENTS' ASSOCIATION.

MR. EDITOR,—According to promise I will give a brief account of the meeting of the Association of Medical Superintendents of American Institutions for the Insane, which was held at the Ocean House, Newport, from June 26th to June 29th, inclusive. This place was selected for the purpose of avoiding the loss of time in excursions to hospitals and other places of interest near the larger cities, while affording sufficient outside attractions of a kind to interest the members and their wives when off duty. It was voted last year to accept no invitations outside of Newport. Committees of three were also appointed to report on nearly a dozen subjects of interest to the specialty, so as to insure sufficient material for discussion. Another innovation was made by which, hereafter, a new president is to be chosen annually, the retiring president to give an address not subject to discussion. The address of Dr. Callender, of Tennessee, which was an eloquent review of the work of the Association, and an earnest vindication of its methods, amply justified this change. Dr. John P. Grey, of Utica, was chosen President, and Dr. Pliny Earle, Vice-President, for the ensuing year.

The new departure, I think, gave general satisfaction, and resulted in a successful meeting. Meetings were held three times daily, and many excellent papers were read and fully discussed. Dr. Clark, of Toronto, read a well digested report on Progress in Cerebro-spinal Pathology; Drs. Gale, of Kentucky, and Rogers, of Indiana, on Certain New Remedies and the Therapeutics of Insanity; Dr. Godding, of the government hospital at Washington, had a paper on the Rights of

the Insane in Hospitals; Dr. Hurd, of Michigan, read a very practical and useful article concerning the Management of the Insane, touching on the treatment of perplexing cases and troublesome symptoms. Dr. Chapiu, of the Willard Asylum, New York, treated of the Relations of the Public to the Insane in Hospitals, and Dr. McDonald, of Ward's Island, New York, gave an account of some annoyances, not to use a harsher term, to which he has been subjected by certain reformers and "protectors of the insane." Dr. Goldsmith described in detail a case of moral insanity coming under his observation. Dr. Fisher, of Boston, was appointed to prepare a memorial sketch of the late Dr. Clement A. Walker, and did so. Dr. Draper read a paper on the Rights of the Insane Outside of Hospitals, and Dr. Andrews, of New York, reported a case of medico-legal interest, in which the plea of insanity was unsuccessfully set up. As I write three weeks after the meeting, and from memory, I may have omitted some paper or action of the Association which should be noticed. If so, I beg every body's pardon.

Harmony and good feeling prevailed as far as I observed. Some of the New York brethren were a little disturbed by the recent shower of writs of habeas corpus which has fallen in that State. Dr. Grey expressed the "sense of the meeting" very well in describing his experience and method of dealing in such cases. Of course the writ must be answered, and a simple statement of facts under oath relieves the superintendent from further responsibility. If the patient is discharged by order of the court, the judge is responsible for the consequences. Judges who make experts of themselves are amenable to public opinion, which must sooner or later become enlightened in regard to the danger from discharged lunatics. Some dying echoes of the Guiteau controversy were heard incidentally to the reading of Dr. Goldsmith's and Dr. Godding's papers, but most members have come to see the necessity of "agreeing to disagree."

As next year is the fortieth anniversary of the Association it was voted to meet in Philadelphia, the original place of meeting, on the second Tuesday in May. This action was taken probably in order that Dr. Kirkbride, who has been in very feeble health, and others of the original membership might once more come together at the place which gave birth to the Association. Dr. Callender's address, which is to be printed, will give much interesting information concerning the early days of the Society. A committee also was appointed to prepare historical and biographical papers pertinent to the occasion. New committees on special topics were also appointed.

In spite of its resolution to avoid junketing the Association received and accepted a few invitations which were the occasion of much pleasure to those who participated, and did not seriously interrupt its programme of work.

The naval squadron, training ship, and Newport Asylum were visited one afternoon, the party embarking in a fleet of sail-boats, under the direction of Dr. H. R. Storer, President of the Newport Medical Society, but for this occasion admiral of the fleet. They were handsomely entertained at the latter place by the mayor of Newport and trustees of the asylum. Returning, the party were received by Dr. Fisher, of New York, Dr. Storer, of Newport, and several of the prominent summer residents of Newport on Washington Street. These glimpses of elegant interiors, of

broad piazzas, of antique fire-places, stairways, and chambers, and the stories of secret passages, false roofs, and smugglers' dark doings in the olden time are very pleasant in the retrospect, and still more so the necessarily brief but cordial welcome of our hosts. One perfect picture of lovely old ladyhood in Quaker costume and genuine antique surroundings will linger long in memory. The Association were also received by the trustees of the Redwood Library, and made an excursion to the Torpedo Station and Fort Adams. The Newport Hospital was open at all times to inspection, and promises to become famous among general hospitals by reason of the large bequest of the late General John Alfred Hazard.

On Saturday the thanks of the Association were voted to the physicians and citizens of Newport for their numerous courtesies, and the members remaining were discharged well pleased, and no doubt, in the language of their annual reports, "much improved."

T. W. F.

Miscellany.

CASE OF "CANCER-DRAWING."

BY ROBERT B. DIXON, M. D.

MRS. W., sixty-eight years old, was hit in the right breast, three years since, by a washing-machine handle which, at the time, was revolving rapidly. The spot, which was on the right side of the breast towards the axilla, became red, tender, and slightly painful. These symptoms continued for several days and then disappeared, leaving a slight hardness which continued and slowly increased in size. There was no accompanying pain, nor did retraction of the nipple follow. She, at any time, did not consider her symptoms sufficiently severe to consult a physician.

In January last, while visiting friends at one of the near suburban towns of this city, she was led to apply to a woman who extensively advertises herself as an "M. D.," a "graduate from a New York Medical College," and a specialist in the treatment of cancer, which she removes "without cutting, ether, caustic, or pain." This woman pronounced Mrs. W.'s case to be cancer of the breast, and said it should be removed at once, and also said she would "guarantee a cure by drawing it out."

Treatment was begun at that time by the application of a paste which was put on in a circle around and near the nipple. This application was continued daily for nineteen days, the paste being rubbed on a little lower down each day, till finally the base of the breast was reached. This paste, which was caustic in some form, ate rapidly into the tissues, at the same time producing intense pain, which during the night time became almost unbearable. Up to this time Mrs. W. had been going to the woman's office daily, but she now became so reduced in strength that the woman began to visit her. Poultices were ordered for the entire breast, and Mrs. W. was told that in nine days "the cancer would roll out like a saucer." These poultices were continued for three weeks, but no cancer rolled out.

At this time Mrs. W. was removed to her home in Maine, and came under the care of my father, Dr. Robert Dixon. Her condition, at this time, was indeed wretched. From a stout, robust-looking woman, in extreme good health, she was now reduced almost to a skeleton, was too weak to move without assistance, and

vomited nearly everything taken into the stomach. The chest wall was in a fearful state. The whole breast had been eaten away by the caustic, leaving a large sloughing sore about eight inches in diameter, from which flowed an abundant fetid discharge. The periosteum on the ribs, from the third to the seventh, had been entirely destroyed; this was followed by death of these ribs, necessitating later on the removal of several pieces, two of which were more than five inches in length, and of the full size of the ribs. At every respiration air whistled through some half dozen holes in the pleura, loud enough to be heard distinctly in an adjoining room. The pain in the side was excruciating, requiring continuous large doses of morphine. The irritable condition of the stomach necessitated rectal alimentation, by which means she was given stimulants and concentrated nourishment in as large and repeated doses as she could retain. Local antiseptic treatment was applied to the chest, and, later, as granulations formed from the chest wall, they were trimmed down with argentic nitrate.

In the course of three weeks the stomach got so it could retain a slight amount of bland nourishment. The granulations formed slowly, and now, six months from the time the paste was applied, cover all of the sore excepting a place the size of a silver dollar; it is doubtful if this spot ever heals over. Through this hole the lung can be plainly seen moving during respiration; the pleura has become firmly adherent to the lung.

Mrs. W. has greatly improved in flesh and strength, and now sits up for several hours each day. For weeks she was so feeble and exhausted that it seemed impossible that she could pull through, and without doubt good nursing and careful attention to alimentation saved her life.

The application of a caustic paste to an entire breast, when there was great doubt of the existence of a cancer to begin with, by an ignorant person, was barbarous in the extreme, and the results to the patient, in this case, horrible.

Boston, June 20, 1883.

SEA BATHING.

THE *British Medical Journal* (June 30th) discourses in a timely manner as to the indications and contra-indications for this practice, which is sometimes a healthy amusement and a therapeutic agent, and sometimes quite the reverse:—

"Shall I bathe?" This is a question which thousands of health-seekers will be asking of their doctors during the next few weeks. While the stimulus of a fresher air, of change of scene, and of new occupations, together with rest from accustomed work, are the elements from which the weakly, the worn, and the worried reap physical and mental restoration in a sojourn on the sea-coast, it is unquestionable that bathing in the open sea is, in itself, a powerful restorative agency, which many persons may employ with very great advantage. The universal experience of our race, through unnumbered ages, has shown the value of sea-bathing in both preventive and curative medicine. A good rule, laid down by an experienced physician, is this: in all cases showing impaired functional powers, without any manifestation of inflammatory symptoms, — in short, in those cases in which the exhibition of alteratives and tonics is indicated, — sea

bathing may, with proper precautions, be resorted to; it is contra-indicated in persons of plethoric habit of body, in cerebral congestion, in organic disease of the heart, in aneurism, and in all persons who have not the ability safely to encounter a comparatively severe shock; while it is also to be forbidden at certain periods in which the female constitution is not prepared for the application of powerful remedies. Because it tends, in certain conditions of impaired health, to cause determination of blood to the viscera, bathing in the open sea is generally unsuitable for persons disposed to congestive disorders of the lungs, kidneys, liver, and brain. Albuminuria, advanced anæmia, and a liability to hæmoptysis are also conditions which are usually accepted as contra-indicating sea bathing. It is hurtful to bathe babies in the sea; children under two years of age are too young to bear with advantage the comparatively severe shock of a cold sea bath. In old age, when the bodily powers are unequal to a vigorous reaction, sea-bathing may do much harm, especially in the subjects of extreme arterial degeneration. In suitable cases, and under proper precautions as to time of bathing and duration of exposure, a daily bath in the open sea is a valuable restorative. In individuals who are fairly robust, it is a stimulant alterative and tonic, promoting appetite, tissue-change, and excretions, and bracing up the nervous, vascular, and muscular systems. Sea bathing is especially useful as a powerful and unsurpassed tonic in delayed convalescence from acute

diseases, in many chronic affections, and in persons whose strength has become enfeebled by injurious excesses, by mental strain, or by unhealthy occupations."

SANITARY REPORT OF THE CONNECTICUT STATE BOARD OF HEALTH.

THE Sanitary report of the Connecticut State Board of Health says:—

"Malarial diseases, as the table of mortality indicates, are becoming more prominent. The commoner forms are dumb ague and malarial fevers, together with the chronic, ill-defined forms, but occasionally a case of congestive chills is seen.

"The eastern part of the State has not as yet been included in the malarial territory, although the line has been pushed to the eastward, and the disease has crept up the border towns at the southeastern end of the State, still there is no general prevalence even where cases have occurred. Generally, where the disease has secured a footing, reports of a greater prevalence are made, that is, comparing the frequency with that of the preceding months. If last year's reports are taken as a standard, a marked falling off is seen, with exceptions, and especially in the mortality. This apparently reached its acme in Connecticut in 1881, for last year shows a decrease of nearly a hundred in the deaths from malarial diseases, and a considerable increase in the mortality from typhoid fever."

Twenty Massachusetts towns.....	156,401	48	7	16.10	25.20	6.30	4.20	2.10

Deaths reported 3843 (no reports from New Orleans and District of Columbia): under five years of age 2214: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 1568, diarrhoeal diseases 1180, consumption 334, lung diseases 168, diphtheria and croup 116, scarlet fever 73, measles 53, typhoid fever 39, malarial fevers 31, erysipelas 19, whooping-cough 17, cerebro-spinal meningitis 17, puerperal fever 15, small-pox eight. From *measles*, New York 17, Baltimore seven, Brooklyn six, Boston and Pittsburg four each, Chicago and St. Louis, three each, Philadelphia and Lowell two each, Cincinnati, Buffalo, New Haven, Worcester, and Cambridge one each. From *typhoid fever*, New York eight, Pittsburg four, Philadelphia seven, Brooklyn, Chicago, and St. Louis three each, Boston, Cincinnati, and Charleston two each, Baltimore, New Haven, Nashville, Holyoke, and Haverhill one each. From *malarial fevers*, New York 12, St. Louis seven, Brooklyn four, Chicago, Baltimore, and Charleston two each, Newton and Northampton one each. From *erysipelas*, New York eight, Brooklyn and Cincinnati two each, Philadelphia, Chicago, Boston, Milwaukee, Newton, and Andover one each. From *whooping-cough*, New York seven, Philadelphia four, Pittsburg two, Brooklyn, Chicago, St. Louis, and Baltimore one each. From *cerebro-spinal meningitis*, New York four, Lowell three, Baltimore two, Philadelphia, Chicago, Cincinnati, Buffalo, Charleston, Worcester, Springfield, and Haverhill one each. From *puerperal fever*, Chicago four, Boston three, Buffalo two, Philadelphia, St. Louis, Milwaukee, Nashville, Worcester, and Fall River one each. From *small-pox*, Philadelphia and St. Louis three each, Boston and Baltimore one each.

Thirty-two cases of small-pox were reported in St. Louis, Buffalo six, Baltimore two; measles 37, diphtheria 17, scarlet fever 12, and typhoid fever six in Boston; scarlet fever 25, and typhoid fever six in Milwaukee.

In 40 cities and towns of Massachusetts, with an estimated

population of 1,186,820 (estimated population of the State 1,922,530), the total death-rate for the week was 22.04 against 16.49 and 16.97, for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending June 23d, the death-rate was 18.7. Deaths reported 3086: acute diseases of the respiratory organs (London) 200, measles 101, scarlet fever 92, diarrhoeal diseases 85, whooping-cough 74, fever 44, diphtheria 17, small-pox (London two, Newcastle one) three. The death-rates ranged from 12.1 in Leicester to 25.1 in Liverpool; Norwich 14; Wolverhampton 15.5; Nottingham 16.5; London 17.6; Newcastle-on-Tyne 18.8; Birmingham 20.5; Sheffield 21.9; Leeds 22.2; Manchester 23.4; Blackburn 23.6. In Edinburgh 17.9; Glasgow 29.7; Dublin 25.2.

For the week ending June 16th, in 166 German cities and towns, with an estimated population of 8,407,157, the death-rate was 28. Deaths reported 4522; under five years of age, 2389; consumption 597, lung diseases 469, diarrhoeal diseases 270, diphtheria and croup 169, measles and röteln 121, scarlet fever 73, typhoid fever 47, whooping-cough 47, puerperal fever 13, small-pox (Berlin two, Thorn and Königshütte one each), four, typhus fever (Elbing one) one. The death-rates ranged from 14.7 in Wiesbaden to 42 in Cologne; Königsberg 30.1; Breslau 35.5; Munich 32.5; Dresden 28.5; Berlin 41.4; Leipzig 17.2; Hamburg 26.7; Cologne 42; Frankfurt a. M. 18.8; Metz 23.9.

For the week ending June 23d, in the Swiss towns, there were 28 deaths from consumption, diarrhoeal diseases 25, lung diseases 18, measles nine, whooping-cough four, diphtheria and croup two, puerperal fever two, scarlet fever one, erysipelas one, typhoid fever one. The death-rates were at Geneva 16.4, Zurich 10, Basle 21.4, Berne 24.8.

The meteorological record for the week ending July 7th in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM JULY 6, 1883, TO JULY 13, 1883.

BAILY, E. L., colonel and surgeon. In addition to his present duties to take charge of the office of medical director Military Division of the Pacific during the absence of the medical director. Paragraph 2, S. O. 64, Military Division of the Pacific, June 30, 1883.

SUTHERLAND, C., colonel and surgeon, medical director Military Division of the Pacific. Granted leave of absence for one month, with permission to apply to the Adjutant General of the Army for extension of two months. Paragraph 1, S. O. 64, Military Division of the Pacific, June 30, 1883.

CAMPBELL, JOHN, lieutenant-colonel and surgeon, medical director Department of the South. Leave of absence on surgeon's certificate of disability granted by S. O. 50, Department of the South, May 21, 1883, extended one month on surgeon's certificate of disability, with permission to leave the Department of the South. Paragraph 7, S. O. 156, A. G. O., July 9, 1883.

PERLEY, HARRY O., captain and assistant surgeon. Assigned to duty at Fort Pembina, D. T. Paragraph 1, S. O. 118, Department of Dakota, July 5, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING JULY 14, 1883.

HUDSON, A., medical inspector, assistant to Bureau of Medicine and Surgery, and Passed Assistant Surgeons S. H. Griffith and E. H. Green granted leave of absence for one month.

BOOKS AND PAMPHLETS RECEIVED. — An Alphabetical List of the Names of all Persons residing in Washington City and the District of Columbia June 1, 1880, aged Seventy-Five Years or more. Compiled from the United States Census Reports of 1880. By J. M. Toner, M. D.

Malarial Poisoning the Cause of Hæmaturia. Reprint from the Transactions of the Medical Association of Georgia at its Thirty-Third Annual Session, 1882. By W. O'Daniel, A. M., M. D., Bullards, Ga. Macon, Ga. 1883.

The Microscope and its Revelations. By William B. Carpenter, C. B., M. D., LL. D., etc. Sixth Edition. Illustrated by 26 Plates and 500 Wood Engravings. Vols. I, II. New York: William Wood & Co. 1883.

Handbook of Electro-Therapeutics. By Dr. Wilhelm Erb, Professor in the University of Leipzig. Translated by L. Patzel, M. D. With 39 Wood-Cuts. New York: William Wood & Co. 1883.

Lectures.**ON MEDICAL EVIDENCE AND MEDICAL WITNESSES.**

ABSTRACT OF A LECTURE DELIVERED AT THE HARVARD MEDICAL SCHOOL.

BY F. W. DEXTER, M.D.,
Lecturer on Forensic Medicine.

It is the object of evidence in its legal sense to establish facts for judicial determination. Such evidence consists of written documents, denominated documentary evidence; and of the depositions, the sworn statements by word of mouth, of living witnesses, — the so-called parole evidence. A distinction is to be made between testimony and evidence; the former includes the latter and is its basis. Testimony is the declaration of a witness; evidence is the effect of that declaration on the mind, or the degree of light which it affords to the point at issue. All evidence, therefore, must be testimony, since the greater includes the less; but all testimony is not evidence.

Parole or oral evidence is derived from two kinds of witnesses, — ordinary witnesses who state facts which have been under their personal observation, and experts, or skilled witnesses, who interpret those facts in the light of their experience or superior knowledge. Ordinary witnesses tell what they know; experts are called to say what they believe, to testify upon matters of opinion. Physicians, like others, are summoned in both these capacities to discharge the functions of both ordinary and expert witnesses; not infrequently to discharge both at the same time in the same trial. They are liable to be called into court as ordinary witnesses because in common with all other persons they may be at any time observers of acts and of the effects of acts of an unlawful character; and they are subject to requisition as skilled witnesses by virtue of their profession and of their acknowledged acquaintance with matters of which court, counsel, and jury are ignorant.

It is obvious that as an ordinary witness a medical man is in the same relation as any individual who speaks of facts within his own knowledge or observation. What is required of him is a memory retentive enough to enable him to recall what he has seen, or heard, or done, sufficient intelligence and acuteness to help him in discerning the usual import of words and deeds, and enough presence of mind to bring out the results of all this at the proper moment in answer to a well-directed system of questioning. Of course the occasions in which you may find yourselves in the relation of an ordinary witness are as varied as is human experience itself. A physician cannot move through life wholly oblivious or unobservant of what is going on around him. He is none the less a citizen because he is a doctor, and his profession gives him no exemption from such civil duties as promote good order and public morality, service on juries and in the militia alone excepted. But his profession inevitably exposes him, more frequently, perhaps, than would any other avocation, to become the witness of unlawful acts, or, at least, of their direct or more remote effects. A man is shot or stabbed; a physician is straightway summoned and becomes a material witness in the case. Poison has been given, a rape committed, a spine injured in a railroad accident, a femur broken in consequence of a defect in the highway, — the doctor is

called in each instance to attend the patient, and having obeyed this summons, he cannot evade the later summons which requires him to tell, under oath, the truth and the whole truth in the cause now in hearing. He finds that he is compelled to practice forensic medicine, whether he likes it or not, and under circumstances which he cannot control.

There is one kind of testimony to which the physician is intimately related by virtue of his office. As you may be aware, the courts reject hearsay testimony as inadmissible; that is, the witness must confine himself to what he himself saw or heard or did, and he cannot present what came to him concerning the case through the interposition or statement of a third party. An important exception to this rule is afforded in the dying declarations of the victims of homicide. The general principle on which this kind of evidence is admitted is derived from the Roman law; it rests on the fact that these declarations are made in extremity, when the patient is at the point of death, and when every motive to falsehood is silenced. A situation so solemn is considered by the law as creating an obligation equal to that imposed by an oath in court. But in order that such declarations may be admitted, it is essential that they be made by the declarant while clearly under a sense of impending death; and this realization on his part must be proved. It is in this connection that the medical attendant becomes important; it is by his testimony mainly that the state of mind of the deceased at the time of the declaration is to be shown. This mental condition of the dying man, his belief in immediately impending death, may be demonstrated by the express language used by him, or may be inferred from his evident danger, or from the opinions of the medical or other attendants stated to him, or from his conduct, or from other circumstances of the case, all of which become matters of evidence.

It is proper that you should know that dying declarations are as admissible when in favor of an accused party charged with the death as when they are adverse to him. It is no objection to their admissibility that they are made in answer to leading questions, or after earnest solicitation, or by signs as well as by words. It is clear that the medical attendant's position in such a contingency is one of great delicacy and responsibility. Every word spoken to or by the deceased, and the order of the conversation, ought to be submitted with the utmost accuracy. Although you may repeat this as oral testimony, it will be of essential help if written notes are made at the time of the declaration. Although it is admitted that the statement of the dying man may be secured by leading questions, I strongly advise you to avoid that method, lest your intentions be misinterpreted; receive whatever is offered to you as the voluntary avowal of your dying patient, but do not become an advocate for the purpose of cross-examining him.

And I may remark, in this connection, that the habit of note-taking, excellent in the ordinary routine of professional work, is of the greatest help in all medico-legal cases. Taylor says that the first duty of a medical jurist is to cultivate a faculty of minute observation, and that it is certainly the fault of medical men that they are not generally better prepared for the questions which are likely to arise in a case on which they know they will be required to give evidence. Thus, in reference to a case on which a charge of murder may be founded, the physician who is called in at

the beginning frequently omits to observe carefully and to note minutely many circumstances, because they appear to him simply trivial or irrelevant, although at the subsequent trial he finds to his dismay that they actually become turning points upon the question of innocence or guilt. Cherish, therefore, the habit of taking detailed and accurate notes in any case which may possibly in the future give rise to a medico-legal inquiry. Be careful of dates; a memorandum of the hour, day, and month of any transaction being frequently of great consequence. If the notes cannot be written on the spot, write them as soon as may be; they lose their value in proportion to their remoteness from the occurrence to which they refer. Save the originals; besides avoiding thus any errors in copying, these first drafts may serve as special mnemonics of the time and circumstances under which they were made. It is often of great assistance to the memory to make a rough sketch of rooms or premises in which dead bodies are found or a homicide has been committed. Do not be afraid of noting too many matters; it should not be left to the policeman to say whether there were any marks of blood on the dress or hands of the deceased, or on the walls or furniture of the room. It is one of the arts of counsel who defend an indicted prisoner to endeavor to discover wherein the medical witness has made errors of omission; the omission may be of no medical importance whatever, but it is usually placed before the jury for much more than it is worth, so that the accused gets the full benefit of any doubt in the matter.

If I were to sum up the qualities of a successful and creditable medical witness in a few words I should say that he possesses (1) the faculty of accurately observing all things about him; (2) a retentive memory; (3) sincerity of purpose and a mind unprejudiced; (4) a well-balanced temperament that will remain unmoved under circumstances of great provocation; and (5) skill in expressing tersely and intelligibly what the mind desires to impart.

I have thus dwelt on the function of the ordinary medical witness because during your earlier professional life you will be called twenty times to fulfill this relation to every single occasion in the more special office of an expert. It is right, however, that you should have some notion of the true sphere of the latter. Expert testimony begins where ordinary testimony ends. Exactly where this point of division lies is a question of some moment to medical men. What are matters of fact as distinguished from matters of opinion? The answer to this comprehends the difference between ordinary and skilled testimony. There can be no doubt of the character of events which lie within the observation of any intelligent person so far as it relates to this question of testimony. If you saw A strike B with a club, B falling immediately, and A running away, it would require no special skill to observe the facts correctly, and to narrate them in court. If, again, you were called as a surgeon to attend B after his injury, and you found a contused scalp wound and a depressed fracture of the skull, with much hæmorrhage from the wound, and brain substance exuding through the fissures in the broken bone, the man insensible, and at length dead, all this is within your ordinary observation as a medical man, and becomes a matter of ordinary testimony in a trial for homicide. But supposing that in a capital trial you listen to all the testimony, and thus become acquainted with a

chain of circumstances each one of which depends on its relation to all the rest for its value and significance in the case, and supposing that at the end you are called upon to interpret the medical circumstances and links in this chain, to connect them harmoniously or to show their incongruity by virtue of their want of harmony with known laws of science with which you are acquainted, then you are an expert medical witness. Or suppose, as in the memorable murder case associated so indelibly with the college building in North Grove Street, that certain mutilated human remains from a privy vault are placed before you, with some half-consumed bones taken from the ash-pit of a furnace, the whole collection comprising only a part of a human body, and you are required, without any knowledge of their real history, to state, under oath, if in your opinion they belong to one and the same body, to build up from these incomplete fragments a probable whole, and thus to establish the central and essential fact, the identity of the victim of a homicide. Surely he who performs this task, as Dr. Jeffries Wyman did in 1850, deserves and receives the highest praise as an expert medical witness.

But between the two extremes which I have here illustrated is a considerable field wherein medical evidence is demanded, but in which the character of the testimony, whether it be ordinary or expert, is uncertain. I refer to cases which do not require the expression of a medical opinion, nor, on the other hand, are concerned with facts of ordinary simple medical observation, but are cases which involve data of common medical knowledge. Can a medical man, summoned as an ordinary witness, and already paid as such, claim the privileges pertaining to an expert before he answers questions requiring medical and technical knowledge for their correct elucidation? In a case of poisoning, for example, can the court compel an ordinary witness, not serving as an expert, to describe the symptoms of poisoning, the time which is required for their full development, the dose which would determine fatal effects, and the post-mortem appearances? The answers to such questions are not matters of opinion, but are matters of fact, supposed to be within the knowledge of all properly educated medical men when they undertake the cure of diseases. Whether the State has any right to this knowledge from an ordinary witness is an open question, which within my own experience has been decided both ways by different judges. In any case, however, whether civil or criminal, in which counsel, examining you as an ordinary witness, enters on that ground, I believe you will have a perfect right to decline to answer except under the formal instructions of the judge. If, therefore, a question comes, more or less remote from the actual facts to which you are testifying, I advise you, for your own comfort and for the sake of your profession, to appeal to the court for instruction whether or not the answer to the question involves expert skill within the meaning of the law, and whether, on that account, you, as an ordinary witness, may not decline to answer it. This may seem a trivial matter to some of you, but it really involves a grave issue, a constitutional right, the right of every man to his own, and the question whether a physician's knowledge of his profession is not thus to be defended.

But the medical expert, fully recognized as such in court, is, in theory at least, in a most honorable and dignified relation. His function is judicial in a certain

sense, for he interprets the meaning of medical facts just as the judge interprets and decides the law. Such being the theoretical function of the expert, what qualities ought he to possess? In the first place the very term expert implies the possession of special and superior qualifications in point of knowledge and experience. He is not presumed to know everything, however convenient omniscience would be on the occasion of the cross-examination, but he is expected to be fully acquainted with the latest and most exact knowledge of the scientific matters concerning which he testifies.

But the ideal expert must not only know the principles of his science, he must also have a special aptitude in applying those principles to the data which are supplied to him; he must have a judicial mind. He will not jump at conclusions, nor form his opinion till he is master of the facts on which he is to base that opinion. The most successful expert will thrive better by deliberation rather than by intuition.

But he will be cautious in stating his conclusions as well as deliberate in forming them. A really honest purpose will lead him to avoid dogmatism. Every physician of sensibility and intelligence must know the limitations of medical science, and remember how readily the extraordinary knowledge of to-day becomes the ordinary knowledge of to-morrow, how unmercifully the doctrines of the fathers are upset and undermined by the observations of the sons. The conscientious expert will, therefore, be slow to make positive assertions about matters in medical science which require fuller investigation to become settled principles, always recognizing the difference between the possible, the probable, and the absolute.

Finally the expert will be impartial, which is but another way of saying that he will be honest. Properly speaking he is not a witness on either side; he does not testify to facts which form the basis of the judgment; he is not concerned with the result. When he has stated what certain proven facts indicate from the medical point of view his office ends. He is not to answer with regard to the accused, Is he guilty? Is he insane? Those questions are for the jury. "Every witness," says Lord Hatherly, "should eschew altogether the notion of partisanship. He should be ready to give his opinion frankly and unreservedly, regardless how it may tell. He is there not as an advocate, but in order to inform the court and jury to the best of his judgment."

(To be concluded.)

Original Articles.

NEURASTHENIA; ITS CAUSES AND ITS HOME TREATMENT.¹

BY J. S. GREENE, M. D., OF DORCHESTER.

THE word Neurasthenia is here taken, not attempting an accurate definition, to signify that state of exhaustion, reduction, or suspension of available nerve power popularly known as nervous prostration. It is scarcely necessary to add that this is a condition entirely distinct from anæmia, and also from hysteria, though these diseases may be associated with it, and are possibly sometimes mistaken for it.

In the discussion which followed the reading of a paper on Subinvolution of the Uterus and Neurasthenia, before the Boston Society for Medical Observation, about two years ago, Dr. Weir Mitchell said that he preferred to use the term nervous exhaustibility rather than nervous exhaustion. The distinction is obviously a valuable one, but the latter term has a convenience and fitness if used simply as the expression of the ultimate condition whereof the liability or predisposition is signified by the former. In the remarks which follow both terms will be made use of, according to these their primary and natural meanings. It is not only convenient but necessary, in pursuing my subject, to give to the term nervous exhaustibility a wider significance than did the distinguished authority whom I have quoted.

I take this postulate: That it is nervous debility or nervous exhaustion, nerve-tire or neurasthenia, interchangeable terms, or terms standing for varying degrees of nervous disability, with which we as physicians are confronted in individual patients; while nervous exhaustibility is a characteristic of the age in which we live, and of which we as social scientists and medical philosophers must take account.

I believe that the nervous exhaustibility of the present day has its origin in the immense uprising of mental activity produced by those supreme factors in modern civilization, free schools and a popular press.

When we contemplate the astonishing inventions and discoveries which characterize the age, each in turn eclipsing its predecessors, and each powerfully helping to complicate the maze and impel the dizzying whirl of human activities, we cannot wonder at the evidences of over-tension and the increasing proportion of those who have to pause by the way. The one set of facts is the inevitable and logical complement and accompaniment of the other, and both are directly traceable to the invention of printing.

It seems as if humanity in this age of the world is reaching the end of its tether; that it is putting into action all its capacity, leaving nothing in reserve. The men and women of to-day and their successors, far more than those of former times, are feeling, or are destined to feel, the limitations of their power to do.

A statement of modern tendencies may be formulated thus:—

First. Immense increase and general diffusion of knowledge and rapid inter-communication awaken dormant energies, develop latent capacities, quicken mental activities, and there results nervous exhaustibility. So far all is normal and legitimate.

Secondly. Activity incites to ambition, emulation, competition, hurrying and striving, and there results tension of faculties and super-activity. Here the danger line is reached.

Thirdly. Hurry and competition bring over burden of responsibilities, cares, anxieties, jealousies, distractions, and these are the chief immediate causes of nervous exhaustion.

I necessarily omit from this discussion a class of cases much fewer in number than those with which we chiefly have to deal,—a class where idleness, lack of occupation and of definite purpose are commonly associated with habits of emotional excitement from reading trashy, sensational literature and with practices of vicious self-indulgence. I am not dealing here with the vices, but with the honest errors and natural tendencies which our age has especially developed.

The influences which lead to nervous exhaustion are all-pervasive. They permeate the atmosphere of our

¹ Read before the Massachusetts Medical Society, June 13, 1883, and recommended for publication by the Society.

modern civilization as bacteria do the air we breathe. We are all to a greater or less degree impressible by them; but, like the living microscopic germs, they make their easiest victims of those whose powers of resistance are weakest. It is not effort, it is struggling and striving; it is not business, it is competition; it is not education, it is cramming; it is not social pleasures, it is social emulations and envyings; it is not over-heated rooms and ill-ventilated houses, it is living on too large a scale; in fine, it is not work, it is *worry* that is sapping the energies of our people.

Now starting from the broad postulate here taken, many would reason, as many in fact do reason from a much narrower premise, that the case is well nigh hopeless for the coming generations of Anglo-Saxon stock. I am not of these pessimists. I do not expect that the race is to die out because it has not fully recognized its limitations, any more than I believe that modern civilization is to be given up to anarchy because it contains aspiring elements which ferment and upheave when confined by tyranny. It is possible that the Anglo-Saxon race in America, being foremost in development and therefore first to experience the limitations of human capacity, will also be first to appreciate the risks and to perceive and apply the correctives; will instruct by their example the slower moving peoples as they, in their turn, approach the danger line. With the poison may be found the antidote.

Nor am I of those who think that this whole matter is to be settled by comparisons of columns of figures, and disposed of as a question of vital statistics. It is mainly perhaps a question of mental quality, a something that the census-taker does not reach. No one can assert that mental power is cut down, that the will which dominates the world is weakened, because the nerves, the medium through which mind moves in its material investment, have sometimes to relax their tyranny over the flesh. Indeed it may be that the evil which we are discussing is less serious in its ultimate issue than its present manifestations threaten; inasmuch as it may be in considerable degree a conservative provision, destined to restrain, and thereby to maintain and transmit the forces which shall hereafter lead in the onward march of humanity.

In the mean time, in all the grades of neurasthenia, the one practical issue is *adjustment*; — adjustment of the race to its present environments, — adjustment of the individual to his and her present limitations; and this eminently practical issue is everywhere, with very rare exceptions, a practicable one. I say then that nervous exhaustibility, as a prominent characteristic of modern life, is the natural and legitimate concomitant of the rapid diffusion of intelligence and evolution of ideas; while nervous debility or exhaustion is the untoward result of a failure on the part of the individual, through his own mistakes conjoined to the errors of his progenitors and guides, to properly adjust his activities to his capacities.

It will serve my present purpose to very briefly indicate some of these special errors which may be called errors of mal-adjustment. And first there are ante-natal influences. The parents have the nervous temperament with the possibilities of nervous exhaustion written on every lineament, with probably the tracings of care and fatigue visible beside. The bride has assuredly wearied herself to the last degree with preparing the bridal trousseau and with calls and en-

tertainments and excitements; while the bridegroom with his own late hours at business or dissipation, has very possibly smoked six or eight cigars a day. Then perhaps during the fatigues of a wedding journey, and certainly in the midst of a tumult of social excitements and domestic cares, and of anxieties, not the least of which is the dread of offspring, begins under protest, to the horror and dismay of its progenitors, after numerous postponements secured at the cost of special aggravations of nerve function — begins the new human being.

Without particularizing minutely the progress of this life thus inauspiciously started, there is one other interesting fact of ante-natal influence to take note of. The woman, convinced sorely against her will that she is to become a mother, proceeds to despoil herself of energy after a new fashion. Whereas until now she has worn and wasted her strength in striving to do, henceforth during the term of her pregnancy she will continue the spoliation by striving to *be*, — not therefore, however, omitting the doing. Besides continuing all her wonted activities, she now undertakes unselfishly, for the welfare of the unborn child, to become a saint. She disciplines herself to equanimity and cheerfulness; suppresses feelings of irritability or despondency; resists all temptations to tearfulness; makes herself a very female Mark Tapley for being jolly under adverse circumstances. In this constant effort of will to control emotional manifestations, which are the natural relief of over-tension, she maintains and increases the tension at the expense of her own strength and the vitality of her offspring. In making herself a saint she becomes also a martyr to a mistaken idea of duty.

In proceeding with the subject, it is necessary to remark that the influences acting upon the child and youth are mainly calculated to develop and enhance the nervous excitability implanted in its constitution. These influences can barely be suggested here.

The graded system in the public schools, with the tests for promotion from class to class found solely in percentages of success in repeating from text-books, combined with the large increase in the number of branches required to be studied, and in the number of examinations to be undergone, makes the period of school life, in our day, a period of continuous strain and worry which inevitably results in over-tension. Likewise at home the child is introduced to the excitements of society from the tenderest years. The *boy* is still extant and flourishes under some difficulties; but of what was formerly known as the *girl* there are at present but few living specimens. She is absorbed and merged into the young lady. This young lady, not having had the opportunity to pass gradually from girlhood into womanhood, but having sprung into womanhood from childhood, with almost the celerity with which Venus rose from the sea, brings of organs and functions especially appertaining to womanhood such ill-conditioned equipment that her poor nerves, whether exhausted or not, must be perpetually hampered and fretted, perhaps bullied and half-starved.

Now having instanced some of the most noteworthy among the special exciting causes of neurasthenia, we come to consider its treatment. As already remarked, the successful management of these cases consists in adjusting the patient to the situation; — still better, in aiding and indoctrinating the patient in the principles and practice of self-adjustment. The patient cannot ad-

vance in this without the constant supervision of the physician; nor can the physician succeed without the intelligent and docile coöperation of the patient. Happily this is generally attainable, since the sufferers are usually quite capable of following a train of reasoning to its logical conclusions, and shaping their course of action consistently thereupon. With many their whole scheme of life has been laid upon an impracticable foundation; yet from childhood they have adhered to it heroically in consequence of erroneous teaching, and a mistaken estimate of duty. With such the remoulding of life to a new shape is slow and the work of time. Conviction comes by degrees, precept and doctrine serving as the interpreters of the lessons of stern experience. The physician himself must study with attention each individual case, and patiently form and adopt a plan of management. He will often have occasion to modify this plan to conform to a corrected estimate of the situation, or the powers and qualities of the patient; and the patient should understand this. The physician may often resort to illustrations to enforce his views, and to make clear the situation and the requirements of the case. The patient may be likened to a bank whose specie reserve has been dangerously reduced, and which must contract its business until its reserve is made good; or to a spendthrift, who has squandered his inheritance; or to a merchant, who has expanded his business beyond what his capital justifies, until he comes to the verge of bankruptcy. The one must collect promptly and shorten his credits, and otherwise gradually but steadily and resolutely restore his business to a safer basis; the other must rigidly limit his expenditure until it is sufficiently within his lessened income, with a margin for emergencies.

It may be explained that to have available strength for every-day use always implies the possession of a reserve fund of latent strength lying unseen and dormant like the specie in the vaults of a sound bank; that when, by continuous overdrafts, this reserve has been greatly impaired, more or less continuous but surely prolonged repose must be had without expenditure of nerve power until the nerve centres shall have regained a margin of force without which there cannot be healthful activity. When patients reproach themselves for nervousness, inefficiency, and lack of self-control, and propose to exercise more will and put forth stronger effort, they may be reproached for thinking to further compel by whip and spur the tired, jaded steed which has only too willingly and too patiently borne both burden and abuse.

I object emphatically to patients comparing themselves with others, and repining because they cannot accomplish as much as their neighbor. They need to be taught, as Thomas Carlyle says in *Sartor Resartus*, that "The fraction of life can be increased in value not so much by increasing your numerator as by lessening your denominator."

Very often, in the home treatment of cases of neurasthenia, some member of the family needs to be dealt with, the husband, perhaps, or the wife or the mother, and made to see the situation in its true aspect, to secure a necessary element of coöperative influence. Infelicities of expression and inconsiderate allusions are sometimes the precious prerogatives of a well meaning and well beloved one which cannot be taken away without undue violence, and are harder to neutralize than the spiteful shafts of intentional unkindness. Thus the patient and the environments must be mutually

adapted, and a wholesome mental attitude and moral atmosphere of cheerful tranquillity and patient, persistent hopefulness secured. When this is assured we may feel confident of success in due time. I would discountenance all attempts, however, on the part of the patient to have a time fixed in advance when recovery shall be complete, or even when certain recognized stages or indications of progress shall be reached. Sufficient for the patient that the earliest signs of actual improvement be pointed out by the physician, and that later ones apparent to the patient be verified. Only by observing the rate of real advance can any trustworthy estimate be formed of progress to come; and the physician may disclaim the possession of any other means of judging than this which is common to himself and the patient alike.

The first thing to do on entering upon the treatment of a case of neurasthenia is, to employ the military figure of speech, to sound a retreat; and the question first in order is how far to fall back, and where to make a stand. Sometimes the demoralization is such that there is evidently nothing to do but to retreat promptly to the ships or to the ultimate base of supplies; but very frequently it is justifiable generalship to pause and measure swords with the enemy; and a strongly defensible position may be taken and held considerably in advance of that base.

It may be decided that the patient remain constantly in bed for an undetermined but comparatively brief period; or only that a definite increase be made in the number of hours devoted exclusively to repose. The latter course offers the great advantage of leaving a portion of time daily wherein some, even if but little, exercise in the open air shall be taken. If the former plan be deemed advisable, it may or may not be necessary to introduce passive exercise, — massage or faradization, or both, as a substitute for active movement. If the circulation be feeble, the extremities cool, the skin clammy, and the muscles weak, such measures are distinctly indicated.

A capacity for taking extra sleep is highly to be prized as a means towards restoration; but some there are who cannot spontaneously attain it. If the effects of overstrain be heavily visited upon the brain, causing actual insomnia, restlessness, excitability, it is expedient to compel sleep and a dormant disposition by liberal doses of bromides, perhaps to some extent associated with chloral. In a large proportion of cases I have found an equally available and more satisfactory course than constant stay in bed to be its daily occupancy for twelve, sixteen, or eighteen hours out of the twenty-four, with darkened room and no interruptions except stated ones of the briefest duration for the taking of sustenance. The aim is to secure the largest amount possible of this time of quiet to actual sleep.

The patient may occupy the remaining fraction of the day at discretion, including one, or perhaps two, meals taken with the family, with this stipulation, that as much active exercise out of doors shall daily be taken as the strength will permit.

Generally every form of physical effort within doors, such as standing, ascending and descending stairs, is discountenanced, the powers being reserved for investment in those activities which should bring returns of new strength. There are few so delicate or so exhausted that they cannot bear with benefit, seated over the edge of the bath tub, a dash of cold water down the back from a sponge squeezed over the shoulders; and

many can themselves secure the needful prompt reaction from the slight shock by briskly handling the bath towel. Such efforts, which may be termed the calisthenics of the bath room, should be encouraged according to the patient's powers.

As much food should be taken as can be well digested; and the determination of the amount of repose and of exercise respectively required must often be made more with reference to the working of the function of digestion than of any other function. When a large share of a profound general enfeeblement is visited upon the digestive function to such an extent that the organs of digestion are as indifferent to food as the tissues are disinclined to select and appropriate their pabulum, tonics are often for the time useless, and active exercise impracticable. Here is a case for continuous stay in bed, with passive movements and exclusively liquid diet plied vigorously and systematically. Here the logical necessity of the special plan of management identified with the name of Dr. Weir Mitchell is inexorable up to a certain point.

The total nerve force available is so small that the stomach needs all of it; all functions but those of digestion and assimilation need to be suspended, or at least made merely accessory for a time, and the individual reduced practically to a single organ; — *venter et preterea nihil*. It is merely carrying out to its logical conclusion a principle which needs to be recognized and extensively applied. It is that in neurasthenia, nerve power being deficient or unavailable, and insufficient to go around and give each organ and function a supply, the digestive organs are entitled to a full share reckoned by the standard of normal strength.

The function upon which the whole organism depends for the generation of force has a preferred claim, and only such overplus as there may be after this claim is fully satisfied should be distributed among the other creditors.

Little need be said of the use of medicines. Their rôle is a subordinate one; their usefulness is incidental, but not therefore trivial. A typical case of neurasthenia in a healthy subject may sometimes be successfully managed with scarcely any aid from drugs; but such cases are, perhaps, exceptional. The possible need of bromides has already been referred to. The persistence of distressing headaches will suggest the use of caffeine or some such nervous stimulant. It is at once an indication of, and an aid to, nutrition, that the bowels be free. Constipation, like headache, is often a symptom of neurasthenia, which will disappear under the policy of adjustment. If it do not, laxatives are needed. Medicines to aid the digestion and food tonics will be introduced at the discretion of the physician.

If there be uterine trouble this may sometimes be ignored or disregarded; but it should receive considerable and effective treatment in that class where the local disorder is one which does not yield to general recuperative influence alone, but which remains to vex the nerves and retard the nutrition unless relieved by interference.

In discussing this subject an underlying idea has been that, as a rule, there should be, and generally there is, no place so suitable for the management of neurasthenia as home; and that the family physician should regard such cases as his peculiar charge, and success in their treatment as his duty. The physician who can appreciate and make available the advantages and

resources of the home will find no difficulty in deciding at what point or stage in the treatment of a case a temporary change of scene shall be expedient and desirable; nor will he fail to recognize and set apart in the category those cases, comparatively few in number, where some of the surroundings and influences of home are essentially harmful and radically incapable of adjustment, but remain as an insurmountable bar to the patient's progress. For persons so circumstanced, and for that larger number who are dependent on their own efforts for a livelihood, and whose pecuniary resources cease when their strength fails, admission to an institution for the care and treatment of nervous invalids is a priceless blessing.

My closing word shall be a tribute of respect and admiration for those public benefactors who endow such asylums, and for the physicians who, in the care of the inmates, give without stint, their time, experience, and skill, at the risk of exhaustion of their own reserve of nervous power.

A CASE OF CROUPOUS PNEUMONIA OCCURRING IN A CHILD WITH SERIOUS MITRAL DISEASE. RECOVERY.¹

BY ELBRIDGE G. CUTLER, M. D.

MARY M., thirteen years of age, an inmate of an asylum for girls for some years, was sent to me in July or August, 1882, as she was rather pale and seemed delicate, with the inquiry if she were not a fit subject for a few weeks in the country. The child was rather small and thin, and her face was pale. The visible mucous membranes were a little anæmic, and after a few questions I placed my ear on the chest, expecting to hear at most an anæmic souffle. To my surprise there was a very powerful cardiac impulse with a loud systolic murmur, and on careful examination I found considerable cardiac hypertrophy resulting from disease of the mitral valve. There was a systolic murmur heard loudest at the apex of the heart, and propagated towards the scapula and distinctly audible in the back. The pulmonary second sound was accentuated, and the right side of the heart distended. The patient received small doses of iron and later digitalis, as her feet swelled a little, and went into the country for several weeks. She returned home much invigorated, and I saw little of her till about the 1st of December, when she had several pretty severe epistaxes in the night at intervals; a deep-seated cellulitis at the base of the neck on the right side, requiring incision, came on at about the same time, and rather dragged her down.

At this time, December 1st, the physical examination of the heart was as follows: There was flatness on percussion a little to the right of the sternum at the level of the third intercostal space, which at the fourth rib was one and a half fingers' breadth to the right, and below curved in a little. To the left of the sternum the flatness began at the upper part of the sternal end of the third costal cartilage and extended out in a descending line to one and a half inches beyond the left nipple on the fifth rib. The whole breadth of the heart in its greatest diameter was five and one quarter inches. The circumference of the chest at the nipples

¹ Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, April 11, 1883.

was twenty-four inches. The same systolic murmur was heard, and the pulmonic accentuation was marked. She had to be kept on one floor on account of the dyspnoea provoked by the exertion of climbing stairs. A small quantity of digitalis seemed necessary to keep up the compensation. The Sunday before Christmas the child attended church, and a few days later went to some sort of celebration in the evening. On the afternoon of the 29th of December she was seized with pain in the left side low down and in the back under the angle of the scapula, frequent cough, and at the same time there was urgent dyspnoea, apparently caused by the pain of breathing. The pain and dyspnoea increased constantly till evening, when I saw her. The temperature was then high and the pulse rapid. There was marked cyanosis, orthopnoea, every act of respiration being accompanied by a groan, and the countenance wore a terribly anxious expression. A physical examination revealed nothing further in the lungs or heart. The next day there was no material change in the symptoms, except that the pain and cough were lessened through the frequent use of ipecac and paregoric and a continued use of the digitalis. She had sat upright all night, and the dyspnoea was as great as ever. Towards night a few dry, coarse râles were heard in the middle parts of both lungs. These increased in number and extent till, on the morning of the 2d of January, 1883, they were found to have given place to the marked physical signs of consolidation throughout the lower lobe of the left lung. That is, in place of the previous universal resonance on percussion over both backs there was flatness extending from the inner end of the spine of the scapula obliquely downward and outward to the base of the chest on the left, and reaching well into the left axilla. There was bronchial breathing and bronchophony throughout this entire region, and at the end of inspiration an abundant explosion of very fine dry râles.

The only change in treatment was the ordering of a jacket flaxseed poultice to the entire chest in place of the dry heat previously used, the poultices to be as hot as could be borne and to be renewed every two hours. The symptoms of distress, which had remained stationary up to this the fourth day, continued till night, when she became a trifle easier. On the 3d of the month she was decidedly more comfortable, and could lie down a little lower in bed. In the afternoon all over the centre of the left back coarse moist râles obscured the respiration, and by the next day were heard throughout the whole of the lobe. At night on the 4th they were much diminished, cough had disappeared largely, and the expectoration, which had been hitherto almost none, was a little increased. On the 5th she had a very sore place at the lower end of the back, with considerable redness, tenderness, and swelling. An air-bed and poultices gave relief, so that on the 6th she sat up a little in a chair. Elixir of cinchona was then given. On the 9th, twelve days from the commencement of the symptoms, a physical examination made with the patient stripped showed both lungs perfectly healthy, with no vestige of inflammation. Careful percussion revealed the fact that the cardiac boundaries were not materially altered from those obtained just before the occurrence of the pneumonia.

The treatment consisted of half-teaspoonful doses of paregoric given sufficiently often to control pain and cough, wine of ipecac, small doses of digitalis three

times a day, half an ounce of brandy three or four times a day, jacket poultice, bread-and-milk diet with eggs, and, on convalescence, elixir of cinchona.

I am led to report this case first, because it is interesting to me in presenting a complication of heart disease which I had hitherto observed but once, and, second, because of the small proportion of recoveries in similar conditions where the function of the heart is so much impaired.

The pneumonia found my patient with a heart much enlarged by disease and in a condition where it seemed that the compensation had reached its maximum. On the other hand, she was somewhat reduced by several quite copious hæmorrhages and an inflammatory affection, and at the onset of the symptoms was quite pale and anæmic. To this I attribute her recovery largely, for the cyanosis and dyspnoea as it was were so great as to make me constantly entertain the idea of bleeding, and when I left her after each visit I almost expected to find her dead at the next from exhaustion.

The mortality of pneumonia complicating chronic valvular lesions in adults is high and is variously stated according to the number of cases observed. Thus Huss¹ puts the mortality at 30.4 per cent., irrespective of the presence or absence of compensation, while he found the average mortality from pneumonia to be 10.7 per cent. Fismier² found the mortality to be 77.8 per cent., but his statistics were made up from a relatively small number of cases. In 190 cases occurring in the Boston City Hospital, and reported by Dr. J. H. Borland,³ the complication was observed twice. One was fatal, and the other proving likely to be so the patient was removed by the friends.

Dr. H. C. Haven had a child with insufficiency of the mitral valve and sufficient compensation under observation some months where the pneumonic consolidation occurred over the right lower lobe, and the disease was protracted over several weeks. There were no febrile symptoms. All the physical signs of croupous pneumonia were present except sticky and rusty sputa. Resolution occurred after several weeks. Through the kindness of Dr. Haven I had an opportunity of examining the case.

Most authors unite in speaking of the protracted character of the convalescence when recovery occurs.

RECENT PROGRESS IN DISEASES OF CHILDREN.⁴

BY T. M. BOTCH, M. D.

MALARIA IN CHILDREN.⁵

OUT of one hundred and twenty-eight cases, pains in various parts of the body, and especially in the epigastrium, were complained of in one hundred and one, and in about one third of these it is stated to have been severe. The epigastric pain seemed to have no relation to the taking of food, but came on indifferently at any hour when the malarial paroxysm began, or if slight before it then became more severe. In twenty-nine cases epigastric tenderness was also present, and in some of the patients it was so acute that they could

not bear the weight of the clothing. In almost every instance the pain was promptly relieved by antiperiodic treatment, apparently showing that its dependence on the malarial poisoning was unquestionable. Pains in the splenic and hepatic regions were occasionally complained of. Splenic tenderness was noted in one fifth of the cases, and was often acute. Hepatic tenderness was seen in a few instances, and pains in the back, extremities, and neck were occasionally observed, as was a general cutaneous hyperæsthesia, which was often acute and was noticeably relieved by cinchonidia. The condition of the spleen was recorded in seventy-nine cases; in sixty-four it was found enlarged, and in thirty-eight of these markedly so; in four cases the enlargement was doubtful, and in eleven no increase in size was discovered.

Dr. Holt states that the capsule of the spleen is less resistant than in the adult, and he found that the organ enlarged more readily and quickly in children; he also observed that it subsided quickly, and gives this as a reason for not laying much stress on the absence of splenic enlargement. He found that the spleen unless enlarged did not come in front of the middle axillary line, and that in a considerable number of cases in children the enlargement was liable to be overlooked, from the fact that it was chiefly upwards and backwards. The upper border was frequently as high as the seventh rib, and in several cases as high as the nipple, while it was found below the free border of the ribs in a very much smaller proportion; on this account palpation was of little value except in an extremely small proportion of cases. Enlargement of the liver, though often present, was less constant and marked than the changes in the spleen. Disturbances of the digestive system were almost uniformly present, and were usually pronounced. Vomiting was present in seventy-eight out of one hundred and twelve cases, occurred most frequently at the onset of the paroxysm, and in nineteen was persistent. In almost all the cases complete anorexia existed. A record of the condition of the bowels in one hundred and forty cases showed that they were regular in fifty-eight cases, and that where there was diarrhoea the children were as a rule younger than those in whom constipation existed. Regarding thoracic symptoms, there was in the simple cases nothing beyond a slight bronchial catarrh, which, however, was exceedingly common. Functional troubles connected with the genito-urinary system were noticed in fifteen cases, and of these eleven were females, and ten were patients over six years of age. Retention of urine occurred in three cases, incontinence in six, and in six the micturition was frequent and often painful. Prompt relief followed the use of antiperiodic remedies in almost every instance.

Dr. Holt divides the complications of malaria into the respiratory, the gastro-intestinal, and the nervous. Holt has himself not met with any well-marked cases of laryngeal symptoms of malarial origin, but refers to two characteristic cases reported by Bohn in the *Jahrbuch für Kinderheilkunde* for 1873.

Bronchitis was found to be the most frequent of all the complications, and again and again proved to be intractable until its malarial origin was discovered. Holt believes that in certain acute cases he has found pulmonary congestions analogous in their pathology to the congestions of the spleen and liver. He describes the symptoms as being quite uniform and character-

istic. The invasion was acute, the temperature high, from 104° F. to 106° F., the respirations very rapid, in three or four cases reaching 100 in a minute, and resembling the superficial panting breathing of lobar rather than the labored breathing of lobular pneumonia; the face was often cyanotic, and the pulse varied from 160 to 200 per minute; in one or two cases there was marked drowsiness. The physical signs were usually a slight increase of vocal fremitus, dullness on percussion, usually slight; respiration always high pitched and sometimes broncho-vesicular; resonance of the cry exaggerated, sonorous râles, and occasionally coarse and fine mucous râles; these signs were sometimes general in both lungs, but usually most marked behind and towards the apices, and were at times confined to a single lung, and once to a single lobe. When first seen they were diagnosticated as cases of pneumonia, but their subsequent progress and termination convinced Dr. Holt that they were temporary manifestations of malaria, for patients who were seen in the afternoon with the above-mentioned symptoms would be found on the following morning running about the house, with temperature, pulse, and respiration normal, and only the signs of an insignificant bronchial catarrh in the chest; the attacks would recur on the following days until quinine was administered; marked splenic enlargement was detected in these cases. Pneumonia both lobar and lobular were occasionally found as complications of the malarial fever. Spasmodic asthma of malarial origin was seen in six cases; the attacks occurred frequently, were accompanied by marked splenic enlargement, and were promptly relieved by antiperiodics.

A number of cases were observed where vomiting, or vomiting and diarrhoea, occurred periodically every day or every other day, usually accompanying a febrile attack, the symptoms during the apyrexia being slight or entirely absent; the passages were often streaked with blood and accompanied by tenesmus; the spleen was usually enlarged. These symptoms were but slightly affected by ordinary remedies, but yielded readily to antiperiodic treatment. Schmiedler reports three typical cases of this kind occurring at Breslau, in girls respectively eleven months, two and a half years, and six years old.

The derangements of the nervous system in children, depending upon malaria, are numerous. Neuralgia, though not so common as in adults, yet does occur, and the epigastric pains are often to be regarded as purely neuralgic. Schmiedler reports a case of sciatica in a child two and a half years old, recurring in paroxysms of a tertian type until quinine was administered. Motor disturbances are less frequent than the sensory. In three cases there was paresis of the lower extremities; two of these cases were accompanied by severe pains, and improved rapidly under antiperiodics until a perfect cure took place; the third case was not traced to its conclusion, but when last seen there was some improvement. Various spasmodic disorders have been observed as complications, and of especial interest was a case of torticollis in a boy eight years of age, where every afternoon at about one o'clock there was fever, and the neck became perfectly rigid and rotated to the left side; both these symptoms lasted until he went to bed, and on awaking in the morning he was well, and the neck was perfectly mobile until the time of the paroxysm; he had an enlarged spleen and other symptoms of malaria.

The paroxysms were immediately controlled by quinine and have not returned. Nephritis occurred twice as a complication. The prognosis of malaria in children was found to be good in the vast majority of cases. The acute attacks were usually readily controlled, provided that the patients could be made to take and retain quinine or some of its substitutes, which was often a matter of great difficulty. In the chronic form relapses were apt to take place unless the medicine were continued for a long time or the patient removed from the malarial district. Griesinger found relapses in sixty-four per cent. of the cases from one to ten years of age, and thirty-eight per cent. of those from twenty to thirty years. In regard to the diagnosis of malaria in children Dr. Holt considers that there are many well-marked cases in which the periodicity is wanting, and that the most important single symptom is enlargement of the spleen. From the foregoing analysis Dr. Holt draws the following conclusions:—

(1.) Malaria in early life presents symptoms peculiar to that period, and differs from the same disease in adults as widely as does pneumonia.

(2.) The classification of cases as remittent or intermittent, and the division into hot, cold, and sweating stages as in adults, leads to misapprehensions regarding the course of the disease and confusion in diagnosis.

(3.) In any acute febrile disease presenting an unusual course, the spleen should always be examined, especially in a district as malarial as New York.

(4.) In obstinate cases of diarrhoea or bronchitis not affected by ordinary remedies, especially if these symptoms show a tendency to periodicity, malaria should be investigated as a possible cause.

(5.) Spells of drowsiness and frequent attacks of epigastric pains should always excite suspicion.

(6.) In children it is even more necessary than in adults carefully to interrogate every organ before making a diagnosis where the symptoms are at all obscure.

TYPHOID FEVER IN YOUNG CHILDREN.¹

Dr. Chapin having met with several cases illustrating the difference in type between typhoid fever in early life and in adults has made a careful review of the cases which have been mentioned by previous observers, with the following results: That the cases were really typhoid seems to have been proved by autopsies made by Dr. Janeway at the Catholic Half-Orphan Asylum in New York, where a large number of cases occurred of rather an obscure character, but resembling each other closely in their symptoms, and where the post-mortem examinations showed the typical lesions of typhoid. One of the most remarkable features of the disease in children is the frequent absence of all abdominal symptoms. The bowels may be natural or not infrequently costive. Professor Janeway found that only about one in seventy cases had diarrhoea. It is difficult to locate any abdominal tenderness, as there is usually a general hyperæsthesia. Tympanites is rare. Gurgling not of much value, as it occurs also in a simple diarrhoea. The roseola is frequently absent; in the seventy cases already mentioned only eight cases showed an eruption. The nervous symptoms are not nearly so prominent as in adults. One of the most constant symptoms is a mild bronchial catarrh.

¹ American Journal of Obstetrics, July, 1888.

The spleen is at times found to be enlarged and tender, but the difficulties of ascertaining this condition in young children is so great that as a negative symptom it is of very little value. The duration of the fever varies within much wider limits than in adults. A most peculiar feature in children is that the fever after lasting several days or a week may abruptly subside, seeming to abort in a certain number of cases; only about one half of the cases go on to the full development of the disease, the fever lasting three, five, or ten days and then aborting. Probably the average duration of those cases which do not abort is from two to three weeks. It is most frequent between six and twelve years, but occurs at an earlier age, Professor Jacobi having reported a case where death took place in a new-born baby on the sixteenth day. The mortality is small. It is impossible to distinguish typhoid from malaria during the first two or three days, and it is extremely difficult to diagnosticate between typhoid fever and tuberculosis before the physical signs of the latter disease have become marked.

DIABETES INSIPIDUS.²

Senator, in speaking of the pathological appearances which occur in diabetes insipidus, remarks that the opportunities for observing them are few in number because the disease not only rarely causes death, but also because the patients, on account of the long course of the disease, seldom remain in the hospital. The most frequent changes are found in the brain; inflammatory and degenerative conditions of the fourth ventricle often occur, also tumors in that situation or in the cerebellum; these tumors are tubercular or gliosarcomas; there are also in some cases syphilitic exostoses of the skull, together with gummata of the liver. Prof. E. Hagenbach reports the following case: A girl four and a third years old, and previously healthy, began in the winter of 1879 and 1880 to be very fretful, to drink a great deal of water, and to lose her appetite; soon after she would not take anything but milk and water, and cried out for it in her sleep at night. The renal secretion was very large in amount, and there was decided emaciation. There was no history of injury; the parents were living and healthy, and there were three other healthy children. Hagenbach first saw the child December 23, 1880, after she had been in this condition for a year; she was pale and feverish, very restless and irritable. Nothing abnormal was discovered on examination of the chest. She drank a great deal of water. The specific gravity of the urine was 1004; no albumen; no sugar. December 24th she vomited. December 25th she complained of headache. December 27th there was sudden loss of consciousness, with stiffening of the limbs and a quick pulse. On the following day there was converging strabismus, twitching of the right arm and leg and the right side of the face, and great somnolence. January 2d the pupils were dilated and not reacting, the right pupil being narrower than the left. January 6th death took place without convulsions. The patient passed immense quantities of urine, which it was impossible to measure accurately, during the latter part of her life; the specific gravity varied between 1000 and 1004, and there was no sugar found at any time, although repeated examinations were made. The post mortem showed the principal changes to be cheesy tubercle of the infundibulum; meningeal tubercle and distention

² Jahrb. für Kinderheilk., Band xix., Heft 2.

of the fourth ventricle and the lateral ventricles; tubercular peribronchitis at both apices, with a few fresh miliary tubercles of the left lung; follicular ulceration of the large intestine; interstitial hepatitis; hæmorrhages in the kidney, and hæmorrhagic erosions in the stomach and duodenum.

MELITURIA FOLLOWING SCARLET FEVER.¹

Dr. Zinn, of Bamberg, reports the following case: January 27th a boy, four years of age, previously strong and healthy, and of healthy parentage, was seized with scarlet fever and diphtheria. The eruption faded on the seventh day, and the diphtheria gradually subsided. On the thirteenth day an otitis externa appeared, and stormy vomiting with rapid development of œdema and ascites, the urine now for the first time showing evidence of nephritis, being lessened in quantity, and showing a large amount of albumen and numerous casts and blood corpuscles. In a few days the more dangerous symptoms passed off, the patient being treated with hot baths and injections of pilocarpine, and a diffuse diuresis having set in the œdema and ascites quickly disappeared. Although the appetite improved considerably the little patient's strength did not return, so that he remained in bed during the whole month of March. Early in April, on attempting to walk, he was found to have paralysis of the right leg, which, however, soon passed off under the administration of iron without electricity. At this time also a slight amount of albumen appeared in the urine. The next symptom which presented itself was increased action of the heart, even noticed by the child himself. On the 10th of April the urine had a specific gravity of 1030, and a considerable amount of sugar. The amount of urine passed in twenty-four hours decreased to between 750 and 1000 cubic centimetres. The appetite was good, but not excessive; the thirst was not noticeably increased, and nothing else abnormal was discovered. The child was placed on an exclusively meat diet, with milk, eggs, and red wine, and by the end of April there was only one per cent. of sugar in the urine, and by the middle of May one fourth per cent. From this time the child improved in strength, and was allowed to have a mixed diet, and by the middle of June the urine was free from both sugar and albumen, and the patient soon became as strong and well as ever.

This case is of unusual interest, both from the rarity of its occurrence as a sequela of scarlet fever and from its unusually favorable result. Külz, in his article on diabetes mellitus in Gerhardt's *Handbuch der Kinderkrankheiten*, states that out of 111 cases of this disease only seven recovered. The same author mentions that the cause in two cases appeared to be measles, but no case is attributed to scarlet fever. Redon, in his collection of cases of diabetes,² gives, among other causes, weakness from previous diseases, such as measles, scarlet fever, typhoid, etc. Yet on looking over the original articles from which he gathers his cases scarlet fever in no instance is found to be a cause. Thomas, in Ziemssen's *Handbuch der Allgemeinen Pathologie*, Band i., s. 290, speaks of the appearance of sugar in the urine with cerebral symptoms occurring during the stage of fever in scarlet fever, but not as a sequela of that disease. In view of this case of Zinn's it would

be well during a convalescence from scarlet fever to examine the urine carefully for sugar as well as albumen where the patient does not gain in general strength as fast as he ought to.

PECULIARITIES OF AN EPIDEMIC OF MEASLES.³

Dr. J. Fewsmith makes the following abstract from Demme's article in the *Jahrbuch. für Kinderheilkunde*, Band xix., Heft 2: Out of 224 cases of measles there were thirteen deaths. Twice death was caused by the violence of the poison and the excessive fever on the second day. The duration of incubation averaged ten to twelve days, but in a few cases was only three days. There were some noticeable cases of transitory and hereditary immunity from the disease. The epidemic in Bern began at a time when there was much scarlatina present, and Demme noticed in all the cases of measles a very pronounced angina initialis, and repeatedly measles was rapidly followed by scarlet fever in the same person. A girl suffering from chorea was attacked, and a boy nine years old with obstinate prurigo; the former was freed from her chorea, and the latter from his prurigo. In some cases there was an excessively high temperature with the eruption; two cases with respective temperatures of 42.3° C. and 42.6° C. recovered, while two with temperatures of 42.7° C. and 42.9° C. proved fatal. In three cases there was no fever during the whole course of the disease, and in one case the temperature was subnormal. In four cases there was acute pericarditis, and in three cases acute endocarditis. Moreover there were some cases of glomerulo-nephritis in the desquamation stage of undoubted measles, once even with uræmic symptoms. There were two cases of complicating gangrene, one of the vulva, and one of the lower jaw, both ending in recovery.

New Instruments.

A MODIFIED URETHRAL STEEL SOUND.*

BY D. D. GILBERT, M. D.

SOME time ago Dr. Benjamin Cushing, of Dorchester, showed me some steel sounds, the stems of which he had had turned down in order that while treating a certain case of stricture he might not be embarrassed by the narrow meatus which existed.

During the treatment of the case of multiple stricture to which I have referred, I reached a point where I wanted just such an instrument, but was unable to find it. I therefore got Messrs. Codman & Shurtleff to make for me a set of sounds with the following modifications, exemplified in the following illustration, which represents at its full size the tip of a No. 25, F.

Each instrument, near the point, commenced two sizes (French scale) smaller than that marked as the size of the sound, and gradually increased to the full size about one inch from the point, when it was again gradually decreased to a wire as small as was compatible with proper firmness for the long straight staff of the instrument. Each instrument tapering through two sizes, my set was made to contain only one half the number

² American Journal of Obstetrics, May, 1883.

⁴ Being an abstract of a portion of a paper read before the Dorchester Medical Club.

¹ Jahrb. für Kinderheilk., Band xix., Heft 2.

² Virchow und Hirsch, Jahrb., 1877, Band ii.]

of the French scale — alternate sizes. Moreover, no size smaller than No. 9 was procured, because it would be impracticable to apply the principle to a smaller in-

strument, even if one desired a steel sound of smaller size. . . .

One who has never used such an instrument can hardly conceive the greater intelligence with which an instrument can be used when it is free except at the point where the work is being done.

Sir Henry Thompson, when praising the merits of the French flexible bougie, says the one great principle which must decide for us the question of the kind of instrument to be employed is this: "The passage of an instrument of any kind, even into the healthy urethra, must, per se, be a source of irritation. What kind of an instrument produces the least irritation?" Our own Henry J. Bigelow says that "a patient who is the subject of an old stricture, and has received the usual amount of treatment therefor, becomes a witness of no mean value as to the comfort and success of the means employed." The patient for whom I first had these instruments made, the subject of stricture during ten years, claimed for himself the same reliability which I find Dr. Bigelow has claimed for the class. This is his testimony: "I have had personal experience of most of the bougies in use, both flexible and solid, and I cannot say too much in favor of the comparative comfort of these. A person who has never had the experience can have no idea of the greater ease of the passage of these instruments over that of those which distend the urethra in all parts at the same time." Especially is this the case in multiple stricture, where, with the ordinary instrument, each stricture passed becomes an increasing obstacle to further progress, and an increasing source of suffering to the patient. On the contrary with these instruments, while the patient nerves himself to bear the pain of distention of one stricture, he knows that, as soon as it is passed, there is relief, and he can then breathe free again. And so with the operator, when one stricture is passed the instrument is no longer tightly grasped in the urethra, but will easily pass on, and he can attack the next strictured portion as unembarrassed as he did the first. In fine, what is needed for the treatment, by gradual dilatation, of stricture of the urethra, is an instrument which you can use most delicately, holding it lightly between the finger and thumb, withdrawing it or changing its direction as soon as you are able to perceive an obstruction. The hand is to be educated for the power of *delicately perceiving the characters of the passage by means of the instrument* within its grasp. This instrument without doubt fulfills these conditions far better than the ordinary bougie, either steel or solid.

In addition to what has been said on the score of comfort, etc., when used for sounding the bladder, the small staff of this instrument is free in the urethra, and the manipulations of the operator are much less embarrassed thereby.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M. D., SECRETARY.

APRIL 11, 1883. Meeting called to order at 8.05 o'clock. DR. G. B. SHATTUCK in the chair.

SPECIMEN OF OVARIES AND UTERUS AMPUTATED AT THE CERVIX.

DR. ALBERT N. BLODGETT exhibited a pathological specimen which he had received from Dr. John Homans shortly before the meeting. It consisted of the fundus and body of the uterus, which had been amputated at the cervix. Attached to this was the left broad ligament, the left Fallopian tube, the left ovary, and a sac the size of a large orange, situated at the extremity of the broad ligament. The right ovary was also exhibited, but was detached from the other organs. The right Fallopian tube and broad ligament were not found. Upon the peritoneal surfaces of the uterus and the entire surfaces of the broad ligament were adherent remnants of partially organized blood coagula, which hung as shreddy tufts to every part of the serous surface. Upon the posterior surface of the broad ligament was a sac, the walls of which were composed of dense, shreddy coagula, but which had no present contents. The uterus was deformed, the left horn being greatly distended, forming an oblong, conical pocket, which was impervious at its upper extremity, there being complete atresia of the left Fallopian tube. The right horn of the uterus was apparently normal in size, and relatively very short. The section by which the amputation of the organ had been effected passed through the body of the uterus at a point in which the left Fallopian tube still constituted a separate cavity in the wall of the uterus, thus presenting two openings in the cut surface, one the cavity of the uterus, and the other the canal of the Fallopian tube. The wall of the uterus was very thick and dense on the right side, while on the left it was thinner, and the thickness constantly diminished toward the region of the Fallopian orifice. The tissues are now everywhere wrinkled and contracted, but the uterus is said to have been the size of a child's head at the time of the operation. The present size of its cavity from the seat of amputation to the top of the cavity in the middle line is five centimetres; from the same point to the extreme end of the cavity in the left horn is eleven centimetres. Thickness from front to back through both walls 4.5 centimetres; from side to side six centimetres. The lining of the uterine cavity is apparently normal in every respect, and is thrown into numerous minute folds. The lining membrane of the second cavity differs from the first only in respect to the more natural arrangement and condition of the glandular structures of the mucous membrane, which are, very striking in this particular specimen. Both canals are everywhere surrounded by normal uterine muscular tissue. The ovaries are of nearly equal size and about 4.5 centimetre in length by two centimetres in breadth, and 1.5 centimetres in thickness. Their surfaces are covered by shreds of coagulum, and they are softened and elongated. Upon section of the right ovary a corpus luteum is found in the stage of grayish-yellow absorption, the cavity being linear, and almost entirely

obliterated. The content was a mass of finely granular fatty detritus. No other corpora lutea were here observed. In the left ovary a number of firm, rounded bodies were felt, some of which bulged slightly above the surface, and were the size of a pea. There were also small depressed surfaces upon some parts of the mucous membrane covering the ovary. These upon being incised led to sacs of the size of a pea, which contained blood. The lining membrane was covered with columnar epithelium, the cells of which were often in a state of more or less advanced disintegration. The interstitial tissue of the ovary consisted of a loose, long, spindle-celled connective-tissue structure, soft in feeling, and easily separated. In this ovary no corpora lutea were observed. The left Fallopian tube was found, and its canal followed as far as its junction with the body of the uterus, where there was complete atresia of its lumen. The canal was pervious for a distance of eleven centimetres from the body of the uterus to its point of attachment with the before-mentioned sac contained in the broad ligament, at which situation the Fallopian tube was lost. Nothing like a fimbriated extremity could be discovered. The mucous membrane lining the tube was atrophied, and no ciliated epithelium could be observed. The sac in the broad ligament was a cavity consisting of a membrana propria, quite thick and elastic, which lay in folds, and an outer layer of peritonæum covered with fringes of organized blood coagula like adhesions. The lining of the sac was everywhere covered with a layer of pasty matter of a dull-red color, which proved to be grumous blood. Upon the posterior wall of the sac were found two distinct perforations in the lining membrane which extended through the entire thickness of the membrana propria and peritonæum, and communicated by free orifices with the abdominal cavity. Other small perforations of the lining of the sac led down to deposits of grumous blood in the tissues, varying in size from that of a shot to that of a Lima bean. Upon the peritoneal surface of the broad ligament, near the perforations, was a large mass of blood coagulum, a portion of the hæmatocele below alluded to. No connection between the sac in the broad ligament and the ovary could be discovered, and no afferent blood-vessel could be discovered.

The pathological condition, so far as this can be judged from the specimen, is the following: There was essentially a double uterus, the two Fallopian tubes being prolonged toward the cervix, so that in amputating the body of the organ two distinct canals were found. The orifice of the right tube communicated with the vagina, while there was complete atresia of the lower extremity of the left canal. The secretions of this canal had gradually accumulated so as to cause a great distention of this portion of the uterine cavity. There was a distinct sacculated cavity in the outer portion of the broad ligament, which contained a considerable amount of grumous blood, and which communicated by two separate and independent openings with the peritoneal cavity, and which had evidently given rise to the large amount of shreddy coagulum at the seat of the peritoneal openings upon the broad ligament, and formed the source of the blood found in the pelvis as an old hæmatocele at the time of the operation. Several other perforations of the membrana propria of the sac led to small, isolated hæmorrhagic deposits in the tissues beneath, after the manner of a dissecting aneurism. In some of these small sacs the

blood has the consistency of putty, in others absorption of the blood has progressed to such an extent as to leave only a small deposit of coloring matter in the part. At the seat of these perforations the interior of the large sac is lined with a firm reddish-brown layer, similar to that seen in the cavity of a true aneurism when healing by obliteration.

DR. E. G. CUTLER read a paper upon

A CASE OF CARDIAC DISEASE WITH PNEUMONIA.

He remarked that in the list of cases of heart disease in which pneumonia occurred, tabulated in Vienna, the ratio of mortality was thirty per cent. In Basel the mortality attending the same complication has been reported as seventy-seven per cent. In the City Hospital two cases are recorded, one of which died, and the other was removed by friends after life had been despaired of in the hospital, and probably also died. In the case reported the age of the patient no doubt had something to do with recovery, as children are often observed to be more tolerant of intercurrent diseases than are adults. The degree of compensation in children is also often surprisingly great. In the present case death was momentarily expected for several days in succession. Phlebotomy was thought of, but the heart was acting very well, and the uncertainty of the issue of the case and the unsatisfactory surroundings of the patient made it undesirable to bleed except as a *dernier ressource*. At present the child is pale and anæmic, but is picking up strength. During the pneumonia there was considerable cough, but no expectoration, and resolution took place without the formation of sputa. The disease commenced as a bronchitis, and was quickly followed by pneumonia of the lower left lobe. The temperature was high until the second day, but as the patient began to feel more comfortable the temperature fell to normal.

DR. T. M. ROTCH said that he had often noticed an extraordinary recuperative power in children, and has been much impressed by several recent cases. The first was that of a little girl who was carried to the hospital with œdema and deep cyanosis from valvular deficiency and dilatation of the heart. The cardiac dullness extended from the third interspace to the sixth rib, and laterally to a point two centimetres outside the mamillary line. There was a loud systolic murmur in the axillary region extending to the back. The lesion affected the mitral valve. Under the use of digitalis for a year there was marked improvement in all the symptoms. The symptoms and rational signs were now those of hypertrophy more than of dilatation. There was a much less degree of cyanosis, and œdema had entirely disappeared; there was still dyspnoea upon exertion. Now, however, after another year of treatment, the child presents absolutely no cyanosis, and experiences no dyspnoea upon exertion. She goes to school and plays like other children. The cardiac murmur has entirely disappeared, but the apex of the heart is still depressed, and the organ is somewhat enlarged. No murmur is heard in the axilla nor in the back. In children murmurs may disappear, and organic cardiac disease may be entirely recovered from, though this is never observed in adults. Dr. Rotch alluded briefly to several cases in which organic cardiac lesions had disappeared in children, leaving no trace of their existence. The following one has a most interesting history: Two years ago a boy presented himself for treatment for organic disease of the

heart with these general symptoms: the face was deeply cyanosed, the nose, cheeks, and fingers being decidedly blue. There was enlargement of the left ventricle, with a loud mitral regurgitant murmur heard at the apex, in the axilla, and in the back. There was œdema of the feet, legs, and body. Later there was complete paralysis of the left arm. Since that time the paralysis has entirely disappeared, the œdema and cyanosis are gone, and the patient is an errand boy, and may be seen running about the streets every day. The rational signs remain the same as a year ago, but the boy suffers no discomfort, and calls himself perfectly well.

HERMAPHRODITISMUS SPURIUS MASCULINUS BOVIS.

DR. F. S. BILLINGS exhibited the genital organs of a calf presenting the following very peculiar features:—

Description. External. A one year old calf, light red in color, the property of Dr. Stephen C. Martin, of Boston, who had it at his vaccine farm. Dr. Martin very kindly placed it at my disposal for examination.

Head more male than female. Horns three inches long, and haired to within one inch of their tips. The animal betrayed sexual irritability, and was inclined to be ugly.

On viewing the posterior parts, what most attracted attention was the entire want of a vulva, or anything having the external appearance of the same; directly out from the skin extended an enlarged clitoris, about six centimetres in length, with a semicircular fold of the skin embracing its lower portion. So far as I could discover there was no tendency to erection in this organ. The orificium urinæ was immediately above the clitoris, and not very distinctly visible. It admitted a No. 6 English catheter, which passed in thirteen centimetres before the urine flowed. The animal passed its urine in a spasmodic manner, and often to a distance of eight or ten feet behind it. When one felt of the skin about the clitoris a peculiar convoluted mass could be felt within it and anterior to the clitoris; of this we shall speak later.

No indications of a penis could be felt along the perineal region. No scrotum present. Raphé indistinctly to be seen. Four elongated, round bodies were to be both seen and felt in the position of the testicles, but did not depress the skin, and hung pendant when the animal was standing. Two sets of teats were visible, but no appearance of an udder. The posterior pair resembled those generally seen in bulls, were one centimetre long, and solid. The anterior were more widely separated, two and one half centimetres long, and supplied with a canal, out of which could be pressed a very slight amount of pearly colored fluid.

Internal Examination. A very careful removal of the skin revealed the entire absence of the proper tunics to the testicles, of which there were apparently two sets. The anterior, or true testicles, were five centimetres long and three thick; the supplementary testicles were four centimetres long and two and one half thick, and had a ligamentous connection with the anterior, or true testicles, in which ran blood-vessels and nerves, but no ducts; the epididymis was entirely wanting in this pair, while present by the anterior ones. By the supplementary testicles two ducts, ten centimetres long, were to be seen, one from each, extending sub-pelvic to the penis, or what answered to it, and entering the convoluted mass previously mentioned. A very thin serous membrane covered these organs. On cutting

them open they presented a smooth surface, not spongy, of a peculiar ashen color with whitish striæ running from the centre of the body to the periphery, and a markedly developed corpus lligmori. It was at first thought that these organs might be ovaries, but the appearance of the corpus, as well as the entire absence of every ovarian characteristic, leads me to consider them as rudimentary testicles, notwithstanding the fact that the parenchyma had very little macroscopical resemblance to that of the normal testicle, as well as the want of an epididymis.

The anterior pair of testicles had all the attributes of normal save the embracing tunics; they hung free in a mass of loose connective tissue, from which the cords were easily loosened to the inguinal ring toward which they may be seen extending. The cremaster was well developed. The epididymis was well developed, and the seminal ducts could be traced along the funiculus until they entered the ring. Cross section of these organs gave a parenchyma having the peculiar dark orange yellow customarily seen in the bull; it was spongy and swelled up beyond the level of the thin albuginea. A microscopic examination gave evidence of its true nature, but the cells were all very immature, mostly round and epithelial, and nowhere could I find any traces of spermatozoa. The length of the cords was twenty-four centimetres.

The pelvic conditions were made visible by separation of the arch. Here we saw a very small and exceedingly thick and muscular bladder. The spermatic ducts were seen to enter a bicornated body which at first seemed to be the normal ampullæ, but more exact examination led to the determination that it was a rudimentary uterus. The horns of this organ were about three inches long, the body, or neck, about two. The horns had quite a distinct lumen which united in the body, ending blindly. This uteroid body was immediately above the bladder, and ended bluntly above the penis, where it was intimately connected with it.

The penis. Here we found a singular phenomenon. The urethra did not run *through* the penis, that is, its posterior part, but consisted of a thin-walled canal united to it by loose connective tissue and lying upon it, entering it at the pars cavernosa. From the pars cavernosa with its peculiarly powerful accelerator urinæ (in the bull) to the clitoral termination were to be seen two convoluted masses. It should be here mentioned that in the normal penis of the bull, immediately posterior to the scrotum, there is a sigmoid curvature provided with retractor muscles which are attached to the ischium. We have previously spoken of a convoluted mass to be felt anterior to the clitoris; this proved to be one sigmoid curvature having some resemblance to the normal; about two inches anterior to this was to be seen another convolute coiled, not lengthwise, but composed of three and one half coils, one above another, like a coil of rope. There was no urethra through this portion, which was about ten centimetres.

The only part of the penis which bore any resemblance to normality was the pars cavernosa, about three centimetres long. On opening it the presence of the numerous glandular ostia was made apparent by their entire absence. The caput gallinaginis was very well developed with its peculiar trident-like extensions to be seen in the bull, but there was no evidence of ostia for the seminal ducts. Cowper's gland present. Seminal vesicles wanting. Prostate wanting.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. NANCREDÉ, M. D., RECORDER.

THURSDAY EVENING, June 28th. The President, Dr. TYSON, in the chair.

A SPECIMEN OF RENAL CALCULUS, OXALATE OF LIME.

By J. A. MUSSER, M. D.

A. R., aged thirty-two, a stone-cutter, residing one year in Philadelphia, applied to me for treatment June 5th, bringing with him a sample of his urine. It was bloody, and had been voided without pain during the twenty-four hours prior to this visit. Three months ago, without any cause, he was seized with pain in the left loin. The pain increased in severity, kept him from work, caused faintness, but no nausea or vomiting, did not radiate in any direction save transversely to a slight extent, lasted three days, and was not followed by hæmorrhage. In the intervening three months he was in good health. A jar of the body or any movement did not increase the pain. It may be noted, but is rather irrelevant, that for ten or more years he has always had a weak back, becoming painful when stooping.

Twelve hours after the consultation the same localized pain recurred and continued for twenty-four hours. Suddenly it was relieved, and the subsequent urinary discharges were clear. In three days he had a return of the pain and hæmorrhage simultaneously. The pain increased in severity, and at the height of the paroxysm extended to the testicle and the head of the penis. The paroxysm was relieved by the passage of the calculus I show you by the urethra. The passage of the stone through the ureter was characterized by the most agonizing pain and frequent attempts to urinate.

Microscopical examination of the first sample of urine showed the red color due to blood. A similar examination of his clear urine, as well as the bloody, proved the presence of urate of soda and crystals of the phosphates. The urine was acid.

The diagnosis of renal calculus was not difficult, but the microscopical appearances of the urine led me to infer that the stone was composed of uric acid. With such idea the patient was put on alkaline treatment. The sequelæ proved that the solvent effect of such treatment was of no avail save from the diuretic action of the drugs. Morphia was given to relieve pain.

A portion only of the stone was received, an angular portion having been broken off by the patient. The portion weighs .06 gramme. The exterior is tuberculated; the interior dark in color, bluish; the exterior lamina light-brown. It is exceedingly hard. Chemical examination was made by Dr. Leffman, who reported it to be an oxalate of lime calculus.

HÆMATOMA IN THE UPPER PORTION OF THE MEDIASTENUM PRODUCING DEATH BY SUFFOCATION.

DR. J. T. ESKRIDGE said that he obtained the specimen from a colored man, porter, aged thirty-two years. He had led an irregular life, but it was not positive that he had ever contracted syphilis. During the past winter he suffered from a severe cold on the chest, and was told by his physician that his heart was inflamed. With the exception of slight cough, unattended by any difficulty in breathing, he had considered himself in excellent health, when, on June 10, 1883, after carrying a heavy trunk on his shoulder from the first to the

fourth floor of a hotel at Cape May, he was seized immediately with great difficulty in breathing, and was compelled to seek the open window to prevent suffocation. During the next two days, while still remaining at the sea-shore, he suffered from several attacks of shortness of breath, each lasting from several minutes to an hour or more.

He was admitted to the hospital of the Jefferson Medical College on the evening of June 12th, about sixty hours after the occurrence of the accident. On admission his breathing was so labored that he was unable to speak. He was gasping for breath, and bathed in profuse cold perspiration. Respiration 36, with greatly prolonged expiration; pulse 100; temperature 99.7° F. Inhalations of amyl nitrite and the hypodermic use of morphia and brandy seemed to give relief. The attack lasted about twenty-five minutes. He slept well during the night, and was tolerably comfortable until five P. M. the next day, when he had another paroxysm, which was promptly checked by amyl nitrate, morphia, and dry cups to the chest.

June 14th, A. M. Dr. Eskridge saw him for the first time. The patient was breathing quietly, and said that he felt comfortable. Pulse and temperature were nearly normal. Urine contained neither albumen nor sugar. No cardiac murmur was detected. Lungs were hyper-resonant at their apices. Loud, moist, bronchial râles were present throughout both lungs. In view of the man's former freedom from attacks of dyspnoea he thought that he detected nothing capable of giving rise to so great interference with respiration. The next two days no dyspnoic attacks occurred, and he seemed to be doing well.

June 17th. His breathing was distressing for several hours. Nothing seemed to afford much relief.

June 18th. Severe asthmatic breathing came on at six A. M., and lasted in its worst form about six hours. Chloral hydrate gave some relief. After that paroxysm his breathing did not again become quiet. He died exhausted at seven P. M. the next day. With the exception of occasional headache he did not complain of pain at any time.

Section cadaveris was made by Dr. Parrott, the medical resident, the pathologist of the hospital and Dr. Eskridge being absent from the city at the time.

Thorax. Pericardial sac was completely obliterated by old, firm adhesions between the pericardium and heart. The heart was rather soft, and both ventricles were relaxed, and contained considerable dark fluid blood. Valves nearly normal. Both pleuræ were adherent to the upper portion of the pericardium, and the left pleura was everywhere adherent to the lung. Both lungs were emphysematous at their apices, and considerable lobular emphysema existed. Bronchial tubes were congested, and contained considerable mucus. A semi-solid or rather soft oblong body, about two inches long by one and a half wide, was found lying upon the lower anterior surface of the trachea, imbedded in connective tissue, and firmly held by old adhesions. It occupied a position just above and behind the transverse portion of the arch of the thoracic aorta. Three of the rings of the trachea in the position where greatest pressure was exerted by the semi-solid mass presented a dark color, and one of the spaces between the discolored tracheal rings was nearly ulcerated through from the effects of pressure. On cutting into the tumor it was found to consist of blood more or less clotted. The calibre of the trachea was

greatly lessened at the seat of hæmorrhage. No ruptured blood-vessels were found. No disease was observed in any of the arteries. Abdominal organs were nearly healthy in appearance.

Dr. Eskridge, in his remarks on the case, said numerous cases of rupture of the aorta or of smaller blood-vessels into the trachea, bronchi, œsophagus, or mediastinum, were on record, but in all of them, so far as his knowledge went, death resulted directly from loss of blood. The peculiarity of the case of which he had given a description was the formation of a hæmatoma in the mediastinum. In hæmorrhages into that space the blood usually gravitated to the lower portion of the chest, and the patient soon died from loss of blood. In the case he presented, however, on account of extensive old and firm adhesions of pleuræ, pericardium, connective tissue, and everything else in the upper portion of the mediastinum, a hæmorrhage in that situation must necessarily have been circumscribed, and could have taken place only gradually by dissecting up the adhesions. He thought that the condition of the parts that prevented an extensive hæmorrhage predisposed the smaller blood-vessels, especially the veins of that locality, to rupture. In view of the extensive alterations by means of general adhesions that had taken place at the seat of hæmorrhage, it was not surprising that rupture of a blood-vessel should have occurred when the parts in the anterior region of the neck and upper portion of the chest were suddenly put upon the stretch, as occurred in the act of raising a heavy trunk from the floor and placing it upon the shoulder. From the specimen, as he obtained it, he was unable to say whether the hæmorrhage had occurred from a rupture of the aorta or one of the smaller vessels, or from the bursting of a very small vessel that had become aneurismal. The tearing across of small veins would have been sufficient to give rise to the extravasated blood.

CONGENITAL FATTY TUMOR BENEATH OCCIPITO-FRONTAL MUSCLE.

Presented by DR. NANCREDE.

The tumor was simply presented on account of the rarity of such growths of *foetal origin*. The patient was a child aged sixteen months. The growth was noticed at three weeks, and in consequence must have been of foetal origin as it then was of the size of a bean. It presented none of the symptoms of a fatty tumor except a faint lobulation, the skin moving freely over it, and presenting none of the dimpling so common in lipomata. Its site was peculiar for a dermoid cyst, namely, over the right occipito-parietal region, yet its resemblance was so close that by exclusion it was considered to be a congenital cyst. Upon removal it was seen to be beneath the aponeurosis of the occipito-frontal muscle. Microscopic sections, kindly made with the freezing microtome by Dr. N. G. MacConnell, showed that the growth was a pure lipoma.

ADENOMATOUS GROWTH, APPARENTLY RECURRENT, IN REALITY AN OUTLYING PORTION OF THE MAMMA NOT REMOVED AT A PREVIOUS OPERATION.

Presented by DR. NANCREDE.

The above title really gives the essential points in the history of a patient, aged twenty-three years, upon whom two operations had been performed for a supposed fibroma (adeno-fibroma?) of the breast, which recurring after partial removal of the breast, the whole

organ, it was supposed, had been then removed by another surgeon. Dr. Nancrede had opposed all operation at first, considering the breast was really not the seat of anything beyond a local induration after injury. He had removed the third growth, which, from its history and microscopic appearances, he was satisfied was the result of the irritating drag of the badly-placed cicatrix on a small portion of breast tissue left at the second operation. The clinical lesson taught by this case was clear, namely, the freest possible removal of mammary growths.

Recent Literature.

The Medical and Surgical History of the War of the Rebellion. Part III. Vol. II. Surgical History.

This volume, the completion of which its distinguished author, Surgeon George A. Otis, did not live to see, ends the *Surgical History of the War*.

Its every page attests Dr. Otis's untiring industry and zeal, and it will ever remain a worthy monument to him and to American surgery.

After his death the labor of authorship fell upon the shoulders of Surgeon D. L. Huntington, who, carrying out the plan of his predecessor, has maintained the high character of the work for accuracy and completeness.

The period which has elapsed since the war and the records of the Pension Office have enabled the author to follow up many cases, and thus with accurate knowledge of the final results to estimate the value of different methods of treatment in a manner which adds greatly to the worth of the deductions drawn from the statistics.

The importance of the work as a book of reference is much increased by extensive notes from previous authors, and in many instances complete statistics of all known cases of certain injuries or operations are given for comparison.

In this connection it is interesting to notice how favorably the statistics of success in the civil war compare with those of other armies operating in more settled countries, and possessing from the first a trained medical staff and complete outfit.

The present volume comprises Chapter X., Wounds and Injuries of the Lower Extremities; Chapter XI., Miscellaneous Injuries; Chapter XII., Wounds and Complications; Chapter XIII., Anæsthetics; Chapter XIV., The Medical Staff and *Materia Chirurgica*; Chapter XV., Transportation of the Wounded. Chapter X. begins with the consideration of flesh wounds, and includes a careful account of the cases of wounded blood-vessels and their treatment.

The mortality after ligation of the external iliac artery is found to be twice as great in military as in civil practice.

In a series of 127 ligations of the femoral artery for injuries not attended by fracture the mortality rate was 71.7 per cent. Two successful and four fatal cases of ligation of the profunda are reported.

The popliteal and posterior tibial arteries were each tied in seventeen cases, and in each series the mortality rate was 76.5 per cent. Seven out of ten cases recovered after ligation of the anterior tibial.

In twenty-eight cases amputation was practiced for uncontrollable hæmorrhage with a mortality rate of seventy-five per cent. Twenty-six of these amputations were through the thigh.

Attention is called to the importance of tying above and below the point of hæmorrhage in injuries of an arterial trunk.

The discussion of gunshot fractures of the hip-joint is of the greatest interest. At first sight the results of conservative treatment of these injuries seem most encouraging, but the author by a very rigid examination of these cases shows that probably many of them reported as injuries of the hip-joint were in reality extra-articular and he thus modifies the statistics so that conservatism appears less life-saving than either amputation or excision. The approximate mortality rate which he finally adopts is for conservatism, 98.8 per cent.; for excision 90.9 per cent.; for amputation, 83.3 per cent. Probably, however, some of the successful cases treated conservatively, and rejected from the table on account of uncertainty as to the exact nature of the injury were in reality hip-joint fractures and should count to the credit of this method of treatment, and of the cases treated by operation the successes are probably all reported, while a certain number of unsuccessful operations were doubtless not returned by the operating surgeons.

The following rule is laid down for the treatment of shot wounds of the hip-joint: "Expectant treatment is to be condemned in all cases in which the diagnosis of direct injury to the articulation can be clearly established; primary excisions of the head or upper extremity of the femur should be performed in all uncomplicated cases of shot fracture of the head or neck; intermediary excisions are indicated in similar cases where the diagnosis is not made out till late; secondary excisions are demanded by caries of the head of the femur or secondary involvement of the joint; amputation should be performed: 1. When the thigh is torn off, or the upper extremity of the femur comminuted with great laceration of the soft parts, in such proximity to the trunk that amputation in the continuity is impracticable. 2. When a fracture of the head, neck, or trochanters of the femur is complicated with a wound of the femoral vessels. 3. When a gunshot fracture involving the hip-joint is complicated by a severe compound fracture of the limb lower down, or by a wound of the knee-joint." Next in order come shot fractures of the shaft of the femur.

Nine thousand, eight hundred and seventy-one cases are recorded with the following results: 3467 cases treated conservatively with a mortality rate of 49.9 per cent.; 6229 cases treated by amputation with a mortality rate of 53.8 per cent.; 175 cases treated by excision of portions of the shaft with a mortality rate of 69.4.

To arrive at a fair conclusion as to the comparative merits of conservatism and amputation, primary amputations alone should be considered. The mortality rate for these was 49.8 per cent.; slightly better than after conservatism. Considering that the severe cases were amputated, and the attempts at conservatism made in injuries of less severity, the advantage in point of safety is probably even somewhat greater in favor of amputation. In military surgery the necessity of transportation with imperfect apparatus must decide many cases for amputation in which conservatism could otherwise be properly tried.

With all the difficulties in the way of carrying out the conservative treatment it was found more life-saving in fractures of the upper third of the thigh than high amputation, which was almost uniformly fatal.

The results of fifty-four excisions of the knee for gunshot injury go to confirm the almost universal opinion that this operation should be discarded from military surgery. The mortality rate after it was 81.4 per cent. against 53.8 per cent., the rate of mortality after amputations in the lower third of the femur.

In shot fractures of the lower leg conservatism was triumphant over other methods, partly due no doubt to the fact that the less severe injuries are all credited to it. The mortality rates are as follows:—

In cases treated conservatively	13.8 per cent.
In amputations at upper third	27 per cent.
In amputations at middle third	20.6 per cent.
In amputations at lower third	27.6 per cent.

In excisions of portions of the bones of the leg the mortality was much larger than after the conservative treatment of similar injuries, and the limbs obtained were often very useless.

The treatment of shot fractures of the ankle by conservatism and by excision proved unsatisfactory.

The feet saved by both of these methods were often worse than useless. After excision the mortality rate was twenty-nine per cent.; after conservatism 19.5 per cent. It is, however, to be remembered that the conservative method was adopted in injuries of less severity, and that failures generally came to amputation before a fatal issue.

In amputation at the ankle Syme's method with mortality rate of 25.6 was preferred to Pirogoff's with mortality rate at 28.5 per cent. The stump left by Syme's operation was found better adapted to an artificial foot than that after Pirogoff's. After Pirogoff's operation reamputation was required in 16.3 per cent. of the cases after Syme's in 24 per cent.

In Chapter XII. is an interesting section upon military projectiles and their effects upon the various tissues. The accidental diseases of wounds, too, are treated in this chapter, and the matter upon hospital gangrene is of especial interest. But it would reach beyond the proper limits of a review to even indicate the various directions which these investigations have taken.

The above summary gives some idea of the ground covered, but the thoroughness and comprehensiveness of the researches can only be appreciated after the careful study which they deserve. The appearance and value of the work are much increased by numerous excellent illustrations. America may justly be proud of this contribution, which rightly takes a leading place in surgical literature, and which should convince a doubting Congress that a service capable of such work is worthy of generous appropriations.

A. T. C.

— A special dispatch to the *Boston Advertiser* says: P. J. Sheahy, who served as one of the jurors in the Guiteau trial, has become insane, and will be conveyed to an asylum. His insanity has been gradually developing ever since the hanging of Guiteau, which event seemed to have a powerful effect on a mind that before that time never showed the slightest symptom of weakness. Before the trial he frequently expressed the greatest repugnance to serving on a jury that was to try a man for his life, and after the trial he became morbid on the subject of being in part responsible for a hanging.

Medical and Surgical Journal

THURSDAY, JULY 26, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number: \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE BRITISH ARMY HOSPITAL SERVICES INQUIRY COMMITTEE.

WE gave last week some of the facts in regard to the medical services during the Egyptian expedition, which were intended to serve as an introduction to a short discussion of the evidence before the Committee of Inquiry on the Hospital Service. Our account of the medical service of the campaign was necessarily as brief as it could well be made. Our account of the testimony must be confined to those points which seem the most important and the most striking.

Much of the interest of the inquiry to an outsider naturally centres in the opinion of Lord Wolseley, commanding general of the forces engaged in the expedition.

In regard to the hospital at Ismailia he stated to the committee that he was immensely disappointed with its condition, and thought it very discreditable. Visited it on the 27th. "The hospital was already full; men were lying on the floor on blankets." He referred to the absence of mosquito curtains, and the quantities of flies, and the deficiency of hospital attendants, and pronounced the bread unfit for human food. "Suitable provisions might have been obtained in the bazaars if the medical officers had taken the initiative."

"If there had been a military officer in that place looking after the sick and wounded I am quite convinced that he, having the sympathies of a soldier, and knowing the soldiers, would never have allowed those men to be given that bread. What I wish to say is that I think the presence of a military officer in the Ismailia hospital would have gone far to correct what was wrong."

"The medical men worked as well according to their lights as any officers in the army. The Army Hospital Corps men are very bad nurses. They do not take the same care of the men as the regimental orderlies did. There is a laxity of discipline in the Army Hospital Corps, owing to their being under men who do not know how to look after the men."

"The system of giving medical officers the command of the Army Hospital Corps should be altered. A separate officer should look after the discipline in hospitals."

"There were a great number of cases, I almost think mounting to hundreds, of men who were sent away from Egypt who ought never to have left it. I think that the Medical Department at that time were begin-

ning to feel a little frightened about what had taken place. The hospitals were in such bad order that they got rid of their patients by putting them on board ship, and sending them to England. I think in many instances men were sent off who would have been well in a few days if they had had anything like a good hospital to go to at Ismailia where they could have been fed well and looked after for two or three days, and would have been quite fit to go to work again."

These striking views, taken from his evidence, which covers many pages in the report, have naturally excited some indignation among medical men, who believe his testimony to be unjust, and as representing what he thinks now he ought to have said rather than what he did say at the time of his visit to the hospital at Ismailia. At least in considering his testimony before the committee one must take into consideration his telegram dated the 30th of September: "The Medical Department is working to my entire satisfaction."

In opposition let us hear the testimony of Lieutenant-General Sir John Adye, chief of staff, who visited the hospital on the 25th or 26th:—

"I gave Doctor Stanbury every assistance in landing that was required, but military considerations overrode every other, and the port of Ismailia was blocked by the landing of men, horses, guns, carriages, munitions, and stores. The stress was very great because we had to fight battles at a distance in the desert before we could land the bulk of our troops; but even on the 25th, when I visited the hospital, the wounded were all in bed and surgical operations were being conducted; and I thought a great deal had been done in the way of arrangements, considering that this was an empty building without a chair or a table or a bed in it when I went there on the 22d."

Lieutenant-Colonel Butler, assistant adjutant-general, headquarter staff, said: "The bread was generally condemned, but it was no use condemning it, because the supply of bread was totally inadequate to meet the requirements of the army." "There was bread as well as other things to be got in the market," but "the whole of what there was there was cleared out after an hour."

The flour sent out from England was found to be spoilt, and time was required to replace it. The hospitals were furnished with an abundance of biscuit.

Lord Wolseley put great stress upon the absence of veils and mosquito nets. Mr. Edward Cant-Wall, correspondent of the *Times*, speaking of the hospital at Kassassin, was asked if he saw cradles with nets over them over the men's heads, replied that he did not see them. "But these veils were rather a nuisance than otherwise; they raised the temperature twenty degrees directly they were on, and they must have worried the men more than the flies."

Sir William MacCormac served as a non-official member of the committee, and has appended a series of remarks to their report, giving his personal views upon the Egyptian campaign. He compares the care of the English troops with his own experience in the Anglo-American ambulance at Sedan during the Fran-

co-German war. "When I look back on the six weeks I spent as surgeon-in-chief of that field hospital in Sedan and compare it with the accounts of the manner the sick and wounded were cared for during the recent campaign, I cannot but express astonishment at the character of some of the complaints which have been made against our medical service."

"We were very short handed," at Sedan, "for the great number of wounded suddenly poured in upon us. For a few days we had only horse-flesh to eat, and our bread wholly ran out, although we got every loaf the town bakers could give us. We had other hardships to endure, but no one thought of complaining. Far from it, we were overwhelmed with expressions of gratitude both from officers and men. They saw we were trying to do our best for them."

He refers to the dreaded "Egyptian ophthalmia," which during the Egyptian campaign in the early part of the century was the most formidable disease in the army, the plague only excepted. Of the Indian contingent in that campaign fifty became blind, while the French are said to have sent home one thousand blind men from Egypt. In the present campaign not a single man lost his eyesight, though there were 1494 cases of inflammatory affections of the eyes admitted to the hospital.

The following quotation from Mr. McCormack's remarks seem to cover the whole ground:—

"There were doubtless considerable inconvenience, some privation, some hardship; but inconvenience and hardship are things which may be fairly regarded as inevitable in time of war, and doubly so in a war which was pushed forward with such exceptionable rapidity,—where a base had first to be seized and the transport was dependent on the captured lines of rail and canal, and when all other considerations were made subservient to speedy success. Of course this was rightly so, for rapidity, though it may entail individual discomfort and even hardship, saves in the end the greater number of lives."

"In my opinion the medical officers engaged in the recent campaign displayed the most self-denying devotion to the sick and wounded. The duties and responsibilities imposed on them probably exceeded those of any other branch of the service, and the duties were most ably carried out under very trying circumstances, and in a manner which, if we may judge by accomplished results, could scarcely have been better."

It is impossible in any space which it is proper to devote to the subject to consider all the different phases of the inquiry, or even to mention the recommendation of the committee. Certain unforeseen difficulties are sure to arise in any military expedition, and no man can go to war and carry all the comforts and safeguards of a peaceful community with him. One reason of the outcry was the very shortness of the campaign. There was no opportunity to weed out incompetent men, or to improve on deficiencies which actual service is sure to discover.

In the discussion in Parliament on going into committee on the Wolseley Grant Bill Dr. Cameron offered a spirited vindication of the Army Medical

Department from the charges brought against them by Lord Wolseley, and drew from Lord Hartington, the Secretary of State for War, the admissions that he regretted some of the evidence given by Lord Wolseley before Lord Morley's Committee, that in his opinion the Medical Department did not deserve the blame which had been cast upon them, for there was no break-down, and the service was in process of rapid improvement when the war closed.

The medical corps of the British army may be said to be yet in a transition state. In 1873 the regimental system was abolished by which medical officers were looked upon as belonging simply to the regiment, and the unification or corps system was introduced, but among certain of the household troops the regimental system is still retained. In 1876 the rule was introduced that medical officers should enter the army for ten years only, a proviso which left the service absolutely without candidates for some years, and seriously crippled its usefulness, and even to-day the status of the medical men seems not entirely settled, as General Wolseley in his testimony refused to consider the surgeon-general of the expedition a part of his staff.

It is evident that both the commander-in-chief of the army and the adjutant-general, Lord Wolseley, hesitate to give to army surgeons full control of military hospitals; that the older officers look back with regret upon the pleasanter features of the regimental system, and that the present system is not yet perfect in all details; that the medical men themselves are not fully satisfied with their own position, if we may trust a little pamphlet recently issued by one of their own number, and that wounded officers in field hospitals are not at all inclined to submit to regulations which put them for the time being on an equality with privates in the matter of rations. This latter regulation would evidently have a very different effect upon an army officered as the British army is to a volunteer army fighting for a purpose like our own in the Civil War, or one raised by general conscription. The officer waiting impatiently till the surgeon had attended to a case of secondary hæmorrhage to find whether the attendant was to furnish the brandy of his own prescribing, and the other who allowed his servant to put on one side the kettle in which was cooking the broth for a whole ward, in order that he might have the little dish of his own desire, remind us forcibly—by contrast—of Sir Philip Sidney's cup of water and the dying soldier. Are these examples of the sympathies of a soldier mentioned by Sir Garnet?

The wisdom of giving the surgeons complete control of the general hospitals was abundantly shown during our own war, and is fully recognized in the recommendations of the committee.

We have reason to believe that the reaction from unjust criticism has already begun, and that Lord Wolseley himself desires to discriminate more carefully in his criticisms, as the following item from the *Lancet* of July 7th seems to show:—

"At the distribution of prizes at the Charing-Cross Medical School Lord Wolseley, referring to his past services, acknowledged in warm terms the obligations

he had been under in all his campaigns to the medical officers of the army for the zealous and efficient manner in which they had invariably discharged their important and arduous duties. The medical, like every other department of the army, was affected by the progress made by science, and could not afford to stand still. But while he desired to see some reforms made in it, he must say that no body of officers ever did their duty more zealously than the medical. After the battle of Tel el Kebir the wounded were removed and attended to more promptly than, so far as he knew, had ever occurred before, and while he might have fault to find with some parts of the system he had none to find with the individual officers, whose labors were arduous and very successful.

SANITATION AT NEWPORT.

OUR readers will perhaps remember that an association, composed chiefly of the summer residents of Newport, and known as the Sanitary Protection Association, has been in operation for some time, its object being to afford its members the benefit of the best sanitary counsel, both at the time of building new houses and by inspection from year to year, to guard against defects, and to keep householders informed of valuable improvements which may become known to science. The annual report of this society for the year 1882-1883 by its Secretary, Dr. William C. Rives, Jr., has reached us, presenting a sketch of its work during the year. The JOURNAL has previously alluded to the controversy between this society and the local municipal authorities, the latter claiming that the health of the city was all that could be desired, and that the work of the Association was superfluous if not impertinent. A case of cholera last September, though not of the epidemic variety, called attention to the unsanitary condition of a portion of the town, and the President of the National Board of Health, after examining the case, sided with the Association in its effort to get municipal support for a scientific sanitary supervision. The past year has witnessed a growth of public sentiment in this direction, and we are told that at a recent meeting of the city council a committee was appointed to act in the matter of establishing a special board of health, in the constitution of which it is hoped the Sanitary Association will have a voice.

The long-expected report of the house-to-house survey of Newport, made in the winter of 1881-1882 for the National Board of Health at the instance of this Association, which had been awaited with great interest as being likely to give a correct picture of the condition of the city, was read before the members at a special meeting held in November. The result of this survey, which was carried out in great detail, showed conclusively the bad condition of a large number of premises, and most of the wells in the city proper, refuting completely the statement of those who claim that the condition of the city leaves little to be desired. In the face of these facts the argument that

the death-rate on the whole is low compared with that of many other cities seems very weak. For it is held by experts that Newport has natural advantages which ought to make it an unusually healthy place, and it is reasonable to suppose that with the doing away of sewers discharging above the tide level and the watering of streets with salt water so taken as to be contaminated with sewage and other nuisances, not only will the zymotic diseases diminish, but that inconveniences and the minor ailments (which statistics do not cover) will be sensibly alleviated. The members of the Association think that, contributing largely as they do to the tax roll of the city, they have a right to a hearing in matters which so deeply concern them.

THE PARKMAN PROFESSORSHIP OF ANATOMY IN THE HARVARD MEDICAL SCHOOL.

THE appointment of Thomas Dwight, M. D., as Parkman Professor of Anatomy in the Medical School of Harvard University has lately been announced. Dr. Dwight, as is well known, succeeds Dr. Oliver Wendell Holmes, who resigned nearly a year since, having himself succeeded Dr. Dwight's grandfather, the late Dr. John C. Warren, some thirty-five years ago.

Dr. Dwight has been discharging the duties of his office during the past winter, and brings thereto a ripe experience both as student and teacher of anatomy and of kindred subjects. We think it may be said that he owes his appointment to the fact that he was considered to possess the most thorough knowledge of the subjects he will be called upon to teach of any of our fellow countrymen under middle life whose names were brought to the consideration of the government of the university.

He was for several years Professor of Anatomy in the Bowdoin Medical School, and has been for even longer Instructor in Topographical Anatomy and Histology in the Harvard Medical School. He is the author of *The Anatomy of the Head*, *Identification of the Human Skeleton*, *Frozen Sections of a Child*, and of a number of scattered papers, among which we may mention *Description of the Balneoptera Musculus*, *Structure and Action of Striated Muscular Fibre*, *The Action of the Intercostal Muscles*.

Dr. Dwight received the degree of A. B. from Harvard in 1866, and of M. D. in 1867, is a member of various medical and scientific societies, and was formerly surgeon to the Carney Hospital and to outpatients at the Boston City Hospital. He was for a number of years one of the editors of this Journal, and continues, after eleven years' valued service in that capacity, its reporter upon Progress in the Science of Anatomy.

Our best wishes accompany our predecessor and colleague in the discharge of the new and honorable responsibilities which he is called upon to assume.

— We understand that Dr. Calvin Ellis has resigned the position of Dean of the Harvard Medical School, and Dr. H. P. Bowditch has been elected his successor.

TELEGRAPHY AND HEALTH.

THE conspicuous position in which telegraphers have been placed by the present strike has served, among other things, to call attention to the great demands made by that calling upon the nervous system of those who follow it. The first-class operators all read by sound, and in a large office where a hundred or more receivers are all buzzing at once, the strain upon the organ of hearing as well as upon the cerebral centre of audition, protracted as it is through ten hours daily, is very great. Of course, in this as in every other occupation, it is true to a certain extent that "custom makes it a thing of easiness," yet to discriminate between the longer and shorter dashes in an instrument clicking at the rate of a very large number of words per minute involves, none the less, a very close exercise of the attention even when it is done only for the regular working hours of the day, while those operators who have been obliged since the strike to work double time have been excessively exhausted. The nervous and muscular energy expended by a rapid sender is perhaps still greater. It is on the whole surprising that "writer's cramp" is not more frequent than it is among telegraphers.

It is said that few operators are good for much after the age of thirty-five years.

MEDICAL NOTES.

— Dr. John C. Dalton, the eminent physiologist, has resigned his chair in the College of Physicians and Surgeons of New York. His successor is Dr. John G. Curtis, who for a number of years has been the assistant professor.

— Dr. Theophilus Parvin has been called from the professorship of Obstetrics in the University of Louisville, which he had held for a few months, to the chair of Midwifery in Jefferson Medical College. His successor at Louisville is to be Dr. John A. Ochterlony.

— We have received the seventh bound volume of the *Sanitary Engineer*, a journal whose weekly visits are always prized for the valuable information which it always contains in its special department.

— The present attitude of Mr. Lister in regard to the spray may be learned from a communication to the *Medical Press and Circular*, April 25th. He says: "I have not given up the use of the spray, although I certainly regard it as the least important part of our antiseptic arrangements. Whatever other good it may do it is a very mild form of antiseptic irrigation, and tends to keep the *entourage* of the wound, including the surgeon's hands and instruments, pure. But if I had not a spray-producer at hand I should not on that account omit other elements of antiseptic treatment. I still use the spray in changing dressings so long as the wound is not merely superficial. But far more important than using the spray is it to make a point of covering the wound with some pure aseptic material before beginning to wash the parts which were covered with the edge of the dressing only, and were, therefore, impure. In

other words, I believe one of the commonest causes of failure is dabbling alternately the impure surrounding parts and the pure wound with the same piece of rag, which, though moistened with carbolic lotion, cannot work miracles."

— A gallant Irish practitioner, taking up the cudgels for the ladies, says he can see no earthly reason why women should not be allowed to become medical men.

NEW YORK.

— Secretary Folger has communicated to the New York Emigrant Commissioners his opinion that their powers in the matter of preventing imported paupers, of whom so many have recently been received at this port, from remaining in the country are practically unlimited. The principal steamer companies, it is said, have accepted this view, and have promised to take back all persons brought over by their vessels who may be adjudged by the commissioners to be paupers.

— Dr. R. Osgood Mason having witnessed the drowning of a man from a ferry-boat on which he was a passenger (the man was picked up by another boat) thus comments on the treatment that he received: "This case certainly affords food for thought concerning the methods employed for resuscitating people rescued from the water. Here was a man, apparently in the prime of life, who either fell or jumped into the river. He was uninjured by the wheel of the ferry-boat, and was rescued after being in the water only five or ten minutes. By every doctrine of chances, with fair treatment, he should have recovered. But what was done? He was pulled up the side of the tug-boat Ramapo with a boat hook, laid across the rail, doubled up like a half-shut jack-knife, with his head and body inwards and his legs overboard, and there he was allowed to hang, presumably to get the water out of him. I called out twice to those on the Ramapo, which was in plain hearing distance, to take the man off the rail, and lay him down on the deck, but no notice was taken of the direction, and there he hung as the boats separated. Of course the man died. A person in health could hardly stand such treatment. No one doubts the kind intentions of the crew of the Ramapo, but, on the other hand, it seems incredible that such ignorance and stupidity could exist among men employed about vessels. It is bad enough when landsmen roll half-drowned people on barrels to revive them, but for men whose business keeps them constantly liable to see such accidents treatment such as was resorted to in this instance was inexcusable. Proper rules to be followed in such cases, plainly printed, should be posted in every tug-boat and ferry-boat, indeed, upon every kind of craft that plies about our harbor, and in every place where watermen and 'longshoremen resort.'"

— It will be remembered that in February last a case of asphyxiation by illuminating gas was reported in which the patient, after lying for hours in an unconscious condition, was restored by means of transfusion of blood. A novel law suit has now grown out

of this case, the negro from whom the blood was taken having brought suit to recover compensation for the amount lost at the rate of ten cents a drop. All that he received at the time was five dollars, while he claims that the above price was promised him. On the other side it is denied that any such rate of compensation was agreed to, and that the negro signed a receipt for five dollars in full for all services rendered by him. The court has reserved its decision in the case. It is estimated by counsel for the plaintiff that an ounce of blood contains 240 drops, and eight ounces (the amount drawn) at ten cents a drop would thus be appraised at \$192, the value of the attendance, which was continued through four days, bringing the bill up to \$250.

— On the 10th of July a lad of sixteen died of hydrophobia at Fort Hamilton. About six weeks ago he was scratched by a cat over the left eye and on the back of the neck, and it is surmised that the cat had previously had a fight with a rabid dog, and had received some of the virus on its claws. The animal was killed at the time. Curare was administered hypodermically by Post-Surgeon Vollum, who was called in consultation in the case, with the effect of completely controlling the convulsions and all muscular spasm, and it is believed by him that if the remedy could have been used sufficiently early the patient's life would have been saved. As it was he died from exhaustion induced by the terrific struggle through which he had passed before the curare was administered.

— A fatal case of hydrophobia is also reported from Sag Harbor, Long Island, on the 6th of July, the patient being a young boy, of New York, a pupil at the School of the Sacred Heart of Mercy, located there, who, it is said, was bitten in the face by a dog in November last.

Correspondence.

LETTER FROM ST. LOUIS.

St. Louis, July 10, 1883.

MR. EDITOR, — Since my last letter medical circles have been very quiet. Small-pox has hung on with an unusual tenacity far into the hot weather, and has only gradually faded. Now, however, it is about gone, and the effects of the recent high water are becoming manifest in an increase of malarial and diarrhoeal diseases.

There has been quite a breeze in the St. Louis Medical Society regarding the action of one of their delegates to the Cleveland Convention, whereby the Society has been put in a very false position regarding the Code, and made to seem of the same mind as the New York Society concerning its revocation and the establishment of a new code. Drs. Pollak, Porter, and Love were its delegates, and before starting Dr. Pollak introduced into the local Society a resolution requesting the National Association to revise the existing Code, if in their opinion such revision were necessary. He was instructed to consult his colleagues and the State delegates as to the propriety of presenting such a resolution at Cleveland, and if they concurred

to so present it. Instead of so doing he, without any consultation, writes a preamble and presents a resolution on behalf of the St. Louis Society, advocating the rescinding of the present Code and the framing of a new one. His motion was very objectionable to the meeting, and was quickly tabled. These are the facts in the case, and on the first opportunity the St. Louis Society repudiated his action by a nearly unanimous vote, and by so doing declared itself in harmony with the Cleveland Convention.

The law creating a State Board of Health went into effect July 1st, and the Governor has named the following gentlemen as its members: E. H. Gregory, M. D., W. B. Conery, M. D., P. D. Yost, M. D. (Eclectic), of St. Louis; — Cox, M. D. (Homœopath), of Springfield; J. C. Hearne, M. D., of Hannibal; H. F. Hereford, M. D., of Kansas City, and G. T. Bartlett, M. D., of Poplar Bluff. Dr. Gregory will probably be elected President, and Dr. Conery Secretary. It is expected that the Board will shape its policy after that of the Illinois Board, and be of much service to the profession in the State.

A sad accident occurred at the City Hospital not long ago, by which two patients lost their lives and another was put in great danger. The physician prescribed for each a dose of salts, but by the druggist's mistake a solution of chloral hydrate was given instead. The custom had been to keep these and some other drugs in solution ready for dispensing, and the wrong bottle was taken. The jury found that there were not sufficient grounds for a charge of criminal carelessness, and the druggist was discharged.

Respectfully,

J. B. SHAPLEIGH, M. D.

Miscellany.

TUMORS IN THE TEMPORAL REGION.

THIS subject has been thoroughly investigated by C. Bottez,¹ whose researches are spoken of by the *Revue Medicale* in the following terms: —

"A work altogether remarkable, and one which no one will fail to read whom chance may bring in contact with tumors situated in this region. All the lesions are passed in review, the symptoms, the course, and the possible complications being analyzed with peculiar care. No detail is too minute for the author's notice, and no part of the description superfluous."

The following are the conclusions of M. Bottez: —

Tumors in the temporal region are rare. Some are superficial (outside of the temporal muscle) and are generally either epitheliomata or of a vascular nature (anévrismes angiomes). Others are deep (under the temporal muscle). Such are almost always malignant (sarcomata or carcinomata), more often of osteoperiosteic origin, sometimes coming from the dura mater.

Deep abscesses are rare. Nearly all the deep tumors have as a common characteristic more or less rapid progression, thinning of bone, and even perforation into the cranial cavity, a result which the surgeon should always have in mind when operating in this region.

The form most common, which has to do with sarcoma or carcinoma, is without doubt the encephaloidal.

¹ Contribution à l'Etude clinique des Tumeurs de la Région temporale. Thèse de Paris, 1882.

It is impossible in the actual state of the question to say in presence of a deep tumor whether it is a fleshy or a carcinomatous growth, there existing no absolutely diagnostic sign.

In connection with these investigations the case reported by Bryant in the *Lancet* (January 28, 1883) is of especial interest. The case was that of a girl, aged ten years, who had a tough and almost nonsensitive tumor of rapid growth, behind the left ear, involving the temporal and occipital bones. After a period during which the tumor caused no symptoms whatever appeared headache, vomiting, paralysis of the left facial nerve, and deafness in the left ear. Incision over the mastoid process allowed the escape of a little pus and several pieces of necrosed bone. The paralysis increased, although the hearing improved; there followed intense pain in the neck and back, difficulty in moving the tongue, dysphagia, and finally death with increasing irregularity of breathing.

The autopsy revealed a sarcoma filling the entire posterior temporal cavity. The tumor had flattened the left cerebellar hemisphere as well as the medulla oblongata, compressing the nerve origins from the latter, especially the emerging fibres of the left facial nerve.

ANKLE CLONUS IN RELATION TO THE HEIGHT OF THE INDIVIDUAL.

DR. ALEXANDER JAMES, in the *Edinburgh Medical Journal*, June, 1883, presents the results of a number of experiments on the rate of ankle clonus in healthy individuals, which show a probable relation between rapidity of the vibrations and the distance of the muscles concerned from their nerve centre in the cord. It has been noticed that the knee clonus is for the most part more rapid than the ankle, the elbow more than the knee, and the head the most rapid of all. And the author assumes that this difference in the rate of the clonus is due to the difference in distance of the muscles from their centre in the cord. If this be so, we might expect to find differences in the rapidity of clonus in individuals of different heights; and as the height of the individual depends mainly on the length of his legs, this difference would be best marked in the ankle clonus. That this should be the case is fortunate, inasmuch as this clonus is the one which can be most readily induced by healthy individuals, and consequently is the one which can be most readily timed. *A priori* the author arrives at this conclusion: Assuming that (speaking roughly) the distance between the muscles concerned in the production of ankle clonus and their spinal centre is one yard in individuals a little over six feet in height, whilst in individuals a little over five feet in height it is two feet; and further, supposing that the nerve impulse travels at the rate of 120 feet per second, that the latent period of muscle contraction is $\frac{1}{10}$ sec., and that the time required for a reflex act is $\frac{1}{100}$ sec. Then $\frac{1}{100}$ sec. + $\frac{1}{10}$ sec. + $\frac{1}{10}$ sec. = $\frac{1}{50}$ sec., and $\frac{1}{100}$ sec. + $\frac{1}{10}$ sec. + $\frac{1}{10}$ sec. = $\frac{1}{25}$ sec. In this way the rapidity of the ankle clonus in an individual six feet in height should be $\frac{1}{25}$ = 5.8 per sec., whilst that of one about five feet in height should be $\frac{1}{35}$ = 6.5 per second.

The experiments were performed mostly on robust young men, averaging twenty-three years of age, and all the subjects were selected as presumably healthy persons, at least so far as their nervous and muscular

systems were concerned. The results were as follows:—

In individuals varying in height between six feet and six feet four inches (ten cases) the average clonus was 5.84 per sec., the lowest being 5 and the highest 6.75 per second.

In individuals between five feet six inches and five feet eleven inches (twenty-nine cases) the average was 6.48 per sec.; the lowest being 5.7 and the highest 7.4 per second.

In individuals between five feet and five feet five inches (nine cases, of which two were females) the average was 6.91 per sec.; the lowest being 6.7, and the highest 7.2 per second.

In two cases, females, of four feet eleven inches in height, the clonus was 7.8 and 7.3 per sec.; and in one child, suffering from paralysis, in the Children's Hospital, in height about four feet six inches, the clonus was 7.8 per second.

The author says in comment:—

"A study of these results in this way shows, I think, that the theory with which we started is in the main correct, that is, that, *cæteris paribus*, the rapidity of the clonus bears an inverse proportion to the height of the individual. That there should be great differences in individuals of the same height is, of course, to be expected. We know that the rate of cerebral processes varies as evidenced, perhaps best of all, by the fact that the "cerebral equivalent" requires to be obtained for men engaged in astronomical work, and we may be certain that the "spinal equivalent" will present corresponding variations. To have discussed this point would have required a much greater number of observations. I have no hesitation, however, in saying that individuals of the so-called nervous temperament have a rapid clonus as compared with those who appear phlegmatic; and it appears to me, also, that men who take part in athletic sports have a more rapid clonus than their physically less active neighbors. The influence of sex I can say almost nothing about, but I feel sure that as age advances the clonus tends to become less rapid."

THE RELATION BETWEEN RUBEOLA AND MORBILLI.

We find in the *American Journal of Obstetrics* for April a résumé of an article by Dr. Kassowitz¹ on the above subject. In 1874, Dr. Kassowitz expressed his opinion as against the existence of a specific rubeola, claiming that sufficient proof of it had not been brought forward. He now takes pleasure in reporting from his own observation a very extensive epidemic of röteln, during which in no single case a transmission from röteln to genuine measles could be demonstrated. The symptoms and course corresponded with the descriptions of Emminghaus, one third of the cases showing distinct enlargement of the cervical lymph glands. The contagiousness was undoubted; the incubation was between fourteen and twenty days. According to Kassowitz's observations, rubeola is entirely distinct from morbilli, yet the resemblance is so apparent that he must confess that röteln stands closer to measles than any other disease known to us, and perhaps, he suggests, this resemblance depends upon some micro-organism as yet unknown. He supposes between measles and röteln, as between variola and

¹ Wien. Med. Blatt, 4-6, 1882.

varicella, some connection, but leaves the question undecided. The analogy between variola and varicella on the one hand, and morbilli and rubeola on the other hand, might perhaps consist in this, that *very exceptionally* from the infection of varicella variola might arise as from the infection of rubeola morbilli might arise. In a debate on this question in the London Medical Congress, Cheadle reported an epidemic of mild cases of rubeola closely followed by severe cases, which might have given rise to a suspicion of transmission of rubeola into morbilli. Kassowitz recalls, with a side glance at the micrococci, that micro-organisms are made either benignant or malignant at the will of the experimenter. Variola and vaccinia, which, although their eruptions are so similar, are yet clinically so widely separated that they are always considered two different diseases,

are, in fact, probably identical. Vaccine is variola virus changed by transplantation to another species of animal. He remarks that even the transmission of variola by variolation makes the disease more similar to vaccinia, in that it runs a milder course, and the pustules occur only at the point of inoculation; on the other hand, vaccinia in children who suffer from an extensive moist eczema, often on the tenth or eleventh day causes an extensive pustular development upon the eczematous surfaces, perhaps because the increased fluxion to the diseased portions of the skin carries a greater quantity of micro-organisms. "Let us, then, not be in too great haste to divide once, and for all, from our present stand-point of scientific observation, the cord between rubeola and morbilli, and between variola and varicella."

Deaths reported 4136: under five years of age 2371: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 1691, diarrhoeal diseases 1352, consumption 387, lung diseases 155, diphtheria and croup 99, typhoid fever 48, scarlet fever 45, measles 40, malarial fevers 36, small-pox 20, cerebro-spinal meningitis 15, whooping-cough 14, puerperal fever 13, erysipelas nine. From *scarlet fever*, Philadelphia 11, New York nine, Chicago seven, Baltimore four, Newburyport three, Boston, St. Louis, Buffalo, and Milwaukee two each, Brooklyn, Cincinnati, and New Orleans one each. From *measles*, New

York 22, Baltimore four, Philadelphia, Brooklyn, and Boston three each, St. Louis, New Orleans, Buffalo, Worcester, and Cambridge one each. From *malarial fevers*, New York 19, New Orleans eight, St. Louis four, Brooklyn and Chicago two each, Charleston one. From *small-pox*, New Orleans 17, Philadelphia three. From *cerebro-spinal meningitis*, New York, Philadelphia, Chicago, and Lynn two each, St. Louis, Cincinnati, Buffalo, Lowell, Worcester, Fall River, and Springfield one each. From *whooping-cough*, New York and District of Columbia three each, New Haven two, Philadelphia, Brooklyn, Baltimore, New Orleans, Pittsburg, and Springfield one each. From

puerperal fever, Chicago three, Philadelphia, Boston, and Pittsburgh two each, Providence, New Haven, Cambridge, and Haverhill one each. From *erysipelas*, New York, Philadelphia, and Chicago two each, Buffalo, Cambridge, and Springfield one each.

Seven cases of small-pox were reported in St. Louis; scarlet fever 19, measles 13, diphtheria 13, and typhoid fever 11 in Boston; scarlet fever 13, and diphtheria three in Milwaukee.

In 36 cities and towns of Massachusetts, with an estimated population of 1,112,069 (estimated population of the State 1,922,530), the total death-rate for the week was 27.01 against 20.04 and 16.49, for the previous two weeks.

For the week ending June 23d, in 170 German cities and towns, with an estimated population of 8,625,811, the death-rate was 26.8. Deaths reported 4453; under five years of age, 2440; consumption 600, lung diseases 378, diarrhoeal diseases 332, diphtheria and croup 155, measles and *rötheln* 126, scarlet fever 56, typhoid fever 46, whooping-cough 42, puerperal fever 18, small-pox (Breslau, Berlin, and Frankfort a. M. one each) three, typhus fever (Frankfort a. M. one) one. The death-rates ranged from 14.5 in Potsdam to 39.7 in Posen; Königsberg 30.8; Breslau 32.2; Munich 34; Dresden 25.8; Berlin 39.5;

Leipzig 22.7; Hamburg 21.6; Cologne 31.1; Frankfort a. M. 17.3; Straaburg 29.7.

For the week ending June 23d, in the Swiss towns, there were 33 deaths from consumption, lung diseases 20, diarrhoeal diseases 10, diphtheria and croup seven, measles four, *erysipelas* three, scarlet fever one, whooping-cough one, typhoid fever one. The death-rates were at Geneva 14.4, Zurich 18, Basle 15.9, Berne 29.4.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending June 30th, the death-rate was 19.3. Deaths reported 3191: acute diseases of the respiratory organs (London) 226, measles 129, diarrhoea 124, scarlet fever 84, whooping-cough 60, fever 41, diphtheria 22, small-pox (London four, Birmingham two, Manchester and Newcastle-on-Tyne one each) eight. The death-rates ranged from 13.5 in Portsmouth to 27.1 in Manchester; Bristol 14.3; Leicester 16.1; Leeds 17.6; London 18.9; Sunderland 20.2; Birmingham 21.8; Liverpool 23.1; Newcastle-on-Tyne 26.5. In Edinburgh 20.1; Glasgow 28.3; Dublin 26.1.

The meteorological record for the week ending July 14th in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM JULY 13, 1883, TO JULY 20, 1883.

MACGRUDER, D. L., lieutenant-colonel and surgeon, medical director headquarters, Department of the Missouri. Granted leave of absence for one month, with permission to apply for an extension of one month. S. O. 145, Department of the Missouri, July 12, 1883.

ELBREY, FREDERICK W., captain and assistant surgeon. The leave of absence granted on surgeon's certificate of disability by S. O. 26, A. G. O., January 31, 1883, further extended six months on surgeon's certificate of disability. S. O. 162, A. G. O., July 16, 1883.

POWELL, JUNIUS L., captain and assistant surgeon. Assigned to duty at Fort Columbus, N. Y. H. S. O. 130, Department of the East, July 18, 1883.

RICHARD, CHARLES, first lieutenant and assistant surgeon. Assigned to duty at Fort Adams, Newport, R. I. S. O. 130, Department of the East, July 18, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING JULY 21, 1883.

DR. HORACE BROWN SCOTT appointed an assistant surgeon.

CHARLES W. RUSH, OLIVER DIEHL, J. H. BRYAN, and J. D. GATEWOOD, assistant surgeons, promoted to passed assistant surgeons.

C. H. WHITE, surgeon, and A. C. HEFFINGER, passed assistant surgeon, detached from the Lackawanna; the former placed on waiting orders, and the latter granted three months' leave.

T. WOOLVERTON, surgeon, detached from the Naval Hospital, Philadelphia, on the 31st of July, and granted leave of absence for one year, with permission to leave the United States.

BOOKS AND PAMPHLETS RECEIVED.—A Case of Primary Mounomania (Primäre Verrücktheit). By C. B. Burr, M. D., Assistant Physician to the Eastern Michigan Asylum, Pontiac. (Reprint.) 1883.

Experimental Researches of the Tension of the Vocal Bands: (a) The Action of the Thyro-Cricoid Muscle; (b) The Action of the Expiratory Blast of Air. By F. H. Hooper, M. D., Boston, Assistant Physician to the Clinic for Diseases of the Throat, Massachusetts General Hospital, etc.

Pemphigus and the Diseases liable to be Mistaken for It. By George H. Rohé, M. D., Professor of Hygiene and Clinical Dermatology, College of Physicians and Surgeons, Baltimore, etc. (Reprint.) 1883.

The Treatment of the Various Forms of Acne. By George H. Rohé, M. D. (Reprint.) Baltimore. 1883.

Hints on the Treatment of Some Parasitic Skin Diseases. By George H. Rohé, M. D. (Reprint.) 1883.

Seventh Annual Report of the State Board of Health of Wisconsin. 1882.

The Control of Defective Sight on Land and Sea, with especial Reference to the Subject of Color-Blindness. A Résumé of What has been done in this Country and Abroad toward arriving at Proper Legislative Action. Reprinted from the Railway Review. Chicago. 1883.

A System of Surgery, Theoretical and Practical, in Treatises by Various Authors. Edited by T. Holmes, M. A. Cantab., and J. W. Hulke, F. R. S. Third Edition, in Three Volumes. With Illustrations. Surgical Diseases of the Organs of Special Sense, of Innervation and Locomotion, of Respiration and Digestion, and of the Skin.

Lectures.

ON MEDICAL EVIDENCE AND MEDICAL WITNESSES.¹

ABSTRACT OF A LECTURE DELIVERED AT THE HARVARD MEDICAL SCHOOL.

BY F. W. DRAPER, M. D.,
Lecturer on Forensic Medicine.

Now I do not exaggerate when I say that, in practice, the performances of medical experts in America and in England are, as a general rule, a mere caricature of the conduct and acquirements which I have hastily set forth, so deplorably do they fall below the ideal standard. You all know very well the usual course which so-called medical expert testimony takes. In an action at law involving medico-legal questions, the government or the plaintiff retains a medical witness, the best and most serviceable that can be secured, to testify in matters of opinion on and for that side. Inevitably he becomes a partisan, a medical advocate for the party by whom he is employed, and by whose money he is rewarded. He cannot help becoming biased, however honest his intentions may be. He cannot help regarding his professional opinions as so far an elastic material that he may mould or stretch them at will in the interest of his own side and as far as may be against the interest of the opposing side. Ignorant, dogmatic, absurd, and illogical opinions are often presented to court and jury for their instruction, and as representing the best and fullest expression of medical science touching the questions at issue. And then comes the cross-examination, more or less thorough and effective in upsetting the direct testimony, more or less dictated by the medical expert, who usually sits conveniently near the elbow of the examining counsel for the very purpose of suggesting embarrassing questions. Presently comes the turn of the other side, and a medical expert for that party is ready with his opinions to refute and neutralize those previously advanced, swearing stoutly to the effect that the medical expert for the plaintiff is all wrong and unworthy of credence. Thus modern American medical expert testimony comes to be a tilt at contradictions, to the scandal and reproach of the medical profession and the amusement of all the spectators. The very purpose for which the testimony is introduced is largely subverted, and self-respecting physicians have come to feel that there is small honor and less pleasure in this kind of service, and that it is best not to accept invitations to appear as experts, only to be abused by counsel, contradicted by adverse testimony, and made ridiculous before all in the court-room, not to mention that larger audience which reads the newspapers in the world outside.

The causes of all this pitiable business lie partly on a legal and partly on a medical basis. The legal customs and regulations under which expert testimony is introduced tend toward the very abuses described. Each party to a suit may employ without hindrance as much expert testimony as he likes or as he can pay for. This makes the partisanship cumulative. The experts are no longer *amici curiæ* after the fashion of the Roman law, but are medical advocates interested in winning a verdict; sometimes, as in civil suits, they are interested in a peculiar sense from the knowledge

that on the verdict depends their chance of securing the coveted fees through a share of the spoils.

Then when, in addition to this, we recall the license allowed to counsel in cross-examination, the fatal facility with which traps are set so that the witness may stumble and be discomfited, we recognize another of the reasons why this kind of testimony is discredited. The lawyer is hired to gain the case of his client, and it is one of his chief duties to throw doubt over the testimony which is offered adversely to his client's interests.

Another mischievous factor lies in the loose legal limitations and rulings touching the qualifications of those who present themselves as experts. The courts admit as experts many who have not the slightest claim to the title, and whose chief superiority is in impudent self-assertion. A regularly educated physician, whose practice is orthodox, has no advantage over the man whose professional trade-mark is some exclusive dogma or narrow creed. The ignorant old pretender, whose gray hairs cover a minimum of knowledge, is, in the eye of the court, apparently the peer of the brightest and best exponent of medical science. Under such conditions it is not marvelous that expert testimony has become a trade, and that men with a medical diploma stand ready, and are known by lawyers as so doing, to give their services in court for the sake of the fees attached. Nor is it strange that legal writers are willing to discredit all expert testimony because of the deserved reproach which incapable men have thrown upon it. Greenleaf says: "That the testimony of experts in many, if not in most, cases is of little value is universally agreed;" and another author declares that "within the last ten years trials have taken place in which the medical witnesses have done more harm than good, more to mislead the jury than to instruct them."

Now many remedies have been proposed for all this. We hear of no such great abuses and scandals in Germany, where judicial matters connected with medical science are submitted to an impartial commission appointed by the government, and where the medico-legal conclusions are submitted as evidence in writing. In this country it has been proposed that experts, limited in number, shall be appointed by the court, and authorized to make any needed investigations in anticipation of the trial at which they will appear. The effect of this would be that the testimony of such experts, independent of partisan bias, disinterested and free from the mercenary reproach, would carry a weight with a jury altogether greater than mere *ex parte* witnesses selected on account either of their known dogmatism or their convenient pliability. An improvement upon the method here mentioned has been suggested, whereby, instead of leaving the appointment of experts wholly in the discretion of the court, their nomination, prior to their appointment, should rest upon the agreement of the parties at issue, thus securing the element of fairness more fully. To some such improvement in the choice of medical experts we are sure to come sooner or later.

I pass now to matters of more immediate practical concern, namely, to some of your rights and obligations when you become medical witnesses, and to some rules of conduct which will be of service to you in court. And first of the summons. Every witness is entitled to receive a formal written summons before he is obliged to appear in court. This summons, tech-

¹ Concluded from page 75.

nically called a subpoena, is to be left either with the witness personally or at his place of abode, at least twenty-four hours before the trial. In civil cases, it is a rule of the common law, and, in this State, of the statute law also, that a witness shall receive with his summons the fees allowed by law for one day's attendance, and for traveling to and from the court. In criminal cases no tender of fees is necessary on the part of the government to compel its witnesses to attend, it being considered the duty of every citizen to obey a call of this description in a case in which he is himself in a certain sense a party; but if the witness is summoned for the defense in a criminal trial he need not answer except on payment or tender beforehand of his legal fees. If the witness is in the court-room as a spectator at a criminal trial he may be summoned to the witness-stand without the formality of a subpoena.

But if the witness is entitled to a formal call to court he is at the same time under obligation to obey the call. Failure to respond renders the delinquent liable to pay damages to the party suffering loss through his absence, and also to pay a fine not exceeding twenty dollars for a "contempt of the court." Certain "reasonable excuses" are, however, admitted. Physical disability is always a valid cause for indulgence; it is proved by a medical certificate. If a summons is received to attend a criminal and a civil suit at the same hour the criminal trial will have the preference. In other regards the rule of "first come, first served" will hold.

It has been a question of considerable interest with medico-legal writers whether a medical man can be compelled to appear in court as a skilled witness without his consent. Some judicial rulings are recorded to the effect that an expert is not bound to attend at a trial in answer to a subpoena. Thus Lord Campbell: "A scientific witness is not obliged to appear upon being served with a subpoena, and he ought not to be subpoenaed. If the witness knew any matter of fact he might be compelled to attend, but he could not be compelled to give his attendance to speak to matters of opinion." And Judge Sprague, of the United States District Court, affirms the same view. But the most logical, as also the most general, view is that the summons is a peremptory call, not to be construed by the expert or by any one else according to any hypothesis of his own. It is an order for personal attendance in court, and should be obeyed if within the range of physical ability. But once put upon the witness-stand (assuming now that he has no knowledge of the facts of the case at issue) his obligation to the public ceases, and he stands in the relation of any professional man consulted about a subject upon which his opinion is sought. It is evident that the skill and professional experience of a man are so far his own property that he cannot be compelled to bestow it upon a second party; neither has the public, any more than a private individual, the right to extort services from him on the witness-stand; precisely as in his office his opinions may be given or withheld at his pleasure, so far as the control of the court is concerned, and a refusal to express an opinion is not punishable as a contempt of court. Whoever calls for an opinion from him is under an obligation to remunerate him, and he may decline to testify as an expert until the party calling him either pays or has agreed to pay him. When, however, his testimony has been given he has placed it beyond his recall, and

he cannot decline to repeat it or to explain it on cross-examination. The declination must be made, if it be made at all, at the beginning of the direct examination, when the first question requiring the expression of an opinion in the answer is asked. It is the rare exception, however, that these matters give much trouble in practice. In nearly every case the medical witness understands beforehand just the relation which he is to hold to the case, and prepares himself accordingly. It is only when a physician is called as an ordinary witness to testify to facts that embarrassment arises through an attempt on the part of counsel to extract from him gratuitous medical opinions upon medico-legal questions involved in the case; if the witness uses due caution and declines firmly but courteously to be led in that direction his rights will be recognized.

And this leads us to the matter of fees for witness service. These are settled by statute for ordinary witnesses, and to medical men they seem to have been settled in a ridiculously small way. It is a source of much annoyance to physicians that they are obliged to interrupt their business and submit, sometimes for days together, to the inconveniences and delays of a trial in court, and that they are allowed such inadequate recompense, based as it is on the pay of day laborers, and graded, according to the degree of the court, from fifty cents to a dollar and fifty cents for each day's attendance, with allowances for travel at the rate of five cents a mile, "out and home." Fees for expert testimony vary according to the witness's tact in making a good preliminary arrangement, according to the importance of the case, the fullness of the purse which pays the bills, and the expert's opinion of the value of his services. The usual rate is from twenty-five to fifty dollars for each day's attendance. Chemists charge according to the time spent and the difficulty of their work.

Now, once in court as a witness, what rights has the physician in the course of his examination? He has the right that he shall fully understand a question before he answers it; if he does not understand it he has the right and it is his duty to ask its repetition. Some men, and lawyers are not above criticism in this regard, lack the ability to ask questions connectedly, simply, and intelligibly. It thus happens that the most absurd and inconsequent questions are sometimes given to physicians by lawyers in court, not perhaps with the intention to mislead or confuse, but chiefly from unfamiliarity with medical matters.

Some lawyers adopt the ingenious plan of compressing two or three questions before a single interrogation mark. A witness unwittingly answers the last, or the one which fixes his attention. The same answer may not apply to all the queries, but the witness may find too late that it has been made to do double or multiple duty.

A medical witness has the right within certain well-defined limits to refer to notes or memoranda on the witness-stand. The rule of law on this matter is that notes made by the witness coincidentally with or immediately after the occurrence to which they refer may be used to refresh the memory; but if they were made after an interval of weeks or months they cannot be so used. It is not necessary that they shall have been made by the witness himself or be in his handwriting, if only they were made at the time under his inspection. But if the transaction or facts noted have completely escaped from the memory of the witness,

and all he can say is that he believes the memoranda to be true, then they are not allowed.

The general rule as to the inadmissibility of such written evidence is farther departed from in the case of medical or other scientific detailed reports; these the witness is allowed to read, upon the ground that the medical and other facts in the report are generally so numerous and technical that the memory would probably fail to present them with completeness on demand. Much more reliance would be placed on a formal report made out by him when the subject was fresh in the recollection, while there would presumably be no personal interest in the case on the part of the reporter, and his document would thus be above suspicion as to its sincerity.

But an expert is not permitted to quote opinions from books in support of his own position, or in substitution therefor. The author is not under oath. But although the witness, while properly using medico-legal writings to shape his own opinion in the case, cannot otherwise make them available upon the direct examination, yet he may be asked upon cross-examination if he accepts a writer, who is named, as an authority; and, if so, whether a certain opinion expressed in a quotation from this writer is a reliable one, and in accordance with the witness's views. Be sure, before answering such a question, that the quotation is given correctly and in full, with all its qualifying clauses.

A medical witness is entitled, in the next place, to courteous and ingenuous treatment at the hands of counsel. There is a general impression that physicians are the especial objects of abuse from cross-examining advocates; from the lawyer whose client summons you considerate treatment may be expected, but from the counsel for the "other side" some rough handling in the way of questioning may be looked for. Whether right or wrong, the traditional rules of law allow this. Lord Brougham has said that an advocate might do everything in his power to gain his cause, even if the State were ruined thereby; and it sometimes seems to the witness that lawyers believed and practiced this extreme doctrine literally. But while there are some who are notorious for their insolent bearing and unfairness toward witnesses, they do not represent the general tone of the legal profession in this regard at the present day. Mr. Stephen, an eminent British barrister, has remarked that "every contemptuous and even discourteous expression, every query leading nowhere except to the end of confusing the mind or irritating the temper of a witness, ought surely to be reckoned as overpassing the legitimate limits of the counsel's office, and as such be regarded with universal disapprobation." By the majority of lawyers this rule of conduct is recognized, and any considerable departure from it in the examination of a medical witness who shows every appearance of honesty and intelligence in his favor is very apt to injure, in the eyes of the jury, the cause of the counsel who resorts to it.

Professor Taylor says that any advice respecting the manner in which a medical witness should give his evidence, his personal conduct on the witness-stand, is like the directions given to prevent drowning, and is invariably forgotten when the individual is most in need of it. Nevertheless, I venture to add a few hints in conclusion which may be of service. Very much of a medical witness's success evidently depends on his natural temper and self control as well as on his preparation for his examination. Some are diffident, and

suffer from a misfortune which they cannot overcome; others cannot control their speech, their tongues outrunning their judgment and bringing sure discomfiture; others have an irritable temper, and, like Dr. Tuffnell, when they hear the "roars" of the counsel, consider that they have a right to roar also. But to all these, and to others who in spite of themselves are compelled to stand and deliver in court under trying and novel circumstances, the following suggestions may be useful:—

Obviously it goes without saying that a witness should be well prepared on all parts of the subject on which he is to give evidence. But as no man can be expected to know everything, so no one can be hanged for ignorance. Therefore when you are clear that you cannot answer a question without guessing, do not hesitate to say, "I don't know. I cannot give any opinion on that point." You will lose nothing by showing your evident sincerity, and nothing so baffles a troublesome cross-examiner as just such plain sincerity. But having replied in this manner, beware how you are adroitly drawn away from this point by further questions.

Answer all interrogatories directly and decidedly, without ambiguity or evasion, and in a tone of voice to be heard readily by all concerned. "To be accurate," says Tidy, "is a thousand times better than to appear brilliant." The nearer your replies approach the monosyllables "yes" and "no," the better for your comfort and character as a witness. If by a proper consideration of all the facts (and one ought not to express an opinion otherwise) the witness has come to a conclusion for which he can give reasons, his answer should be presented in plain and positive language, free from the suggestion of guessing. One who has not formed a conclusion is not in a position to give satisfactory evidence, and any attempt that he may make to manufacture deductions on the spot will result in disaster to him if the counsel does his duty.

Be deliberate in manner. Think twice before answering. The swift witness always gets into trouble. Have in your mind the remote and indirect as well as the immediate and direct effect of your replies. I do not mean that the witness should be obviously dilatory in answering, for that course would soon result to his annoyance, but the full purport of every question should be comprehended, and its answer should be framed in the mind with some care before it is expressed. Avoid exaggerated language. There is a tendency among physicians to describe their observations in the superlative degree, to say that a part is "intensely" inflamed, or that a hæmorrhage was "extremely severe." The cross-examining lawyer will be likely to compel you to explain your notion of such terms if you have the misfortune to use them.

Especially ought you to be cautioned to use language that can be understood. Recollect that you are speaking not to physicians, but to men who are wholly ignorant of the meaning of medical terms, even of the most ordinary kinds. To the court and the bar such technical words are presumably unintelligible; to the jury they are worse than a dead language. If any one thing more than another has served to render doctors ridiculous and uncomfortable under a cross-examination it is their misfortune in an unconscious habit of using scientific terms. Advantage is always taken to get some fun out of this for the amusement of those in the court-room. Therefore translate your

technical language to suit the comprehension of your auditors; say "skull" and not "cranium," "blood-clot" and not "apoplectic extravasation," and so on through the chapter.

Be on your guard, too, about being drawn into a discussion while on the witness-stand; you will almost always be at a disadvantage; the counsel with whom you engage in controversy is thoroughly at home while to you the situation is a novel and untried one, and your attempt at argument, if you are not exceptionally ready and self-reliant, will almost inevitably end in your embarrassment.

In repeating conversations give as nearly as possible the exact words used by both parties. For example, instead of saying "I asked the prisoner whether he knew anything about the murder, and he denied any knowledge," say, "I said to the prisoner, 'Do you know anything about this murder?'" and he replied 'No, I do not.'" In descriptions involving data of measurements, size, weight, and distance it is better, for the present, at all events until the public mind is more accustomed to the better standard, to avoid the suggestion of affectation, and to use the ordinary English terms instead of the more desirable metric nomenclature. Where absolute accuracy is not required use common and easily understood expressions of comparison, — finger's breadth, size of a silver dollar, size of a five-cent nickel, and so on.

I hardly need to add a word about avoiding partisanship by every power at your command; be fearlessly indifferent how your testimony may affect either side so long as that testimony is true. Answer the questions that are asked, but do not volunteer any statements. But if it should happen that, after having replied to the several questions from counsel on both sides, the witness knows that some material evidence in his possession has not appeared, he may then disclose the new facts to the judge, who would under such circumstances be found to admit them. But one should be very sure that what he is about to impart in this manner is relevant and material, lest he place himself in a false position, and render his motives open to misconstruction. It is right that you should know in this connection that physicians have no legal privileges by virtue of their professional relations to their patients; outrageous as it is to one's sense of honor, professional secrets are not safe from the inquisition of the witness-stand. The only relief lies in an appeal to the judge under such circumstances, and by his decision alone can the witness be guided as to how much of information obtained in the privacy of the sick-room is to be imparted.

And the last word is, that while every medical man should respond willingly to every summons which calls him to court, he should be chary about putting himself in the way of such call. If he considers his personal comfort and mental peace he will shun the court-room as much as he can. It is a place where the physician loses more than he gains in money and in reputation. "I fear not to assert," writes Dr. Gordon Smith, "that the instances in which it has happened that medical witnesses have come down from any judicial examination of importance without suffering more or less injury have not been many; that those in which credit has been gained have been fewer still; and that I know of no instance in which it can be satisfactorily shown that an individual reputation has been thereby established."

A CONTRIBUTION TO THE STUDY OF THE TUBERCLE-BACILLUS.¹

BY HAROLD C. EENST, M. D., JAMAICA PLAIN.

Koch's² announcement in the spring of last year of his discovery of the specific organism lying at the bottom of and being the cause of tuberculosis marks an epoch in the history of this much-discussed pathological problem such as it had never known before.

Beginning with Villemin's³ experiments tending to show the inoculability of tubercle, this subject has attracted attention from the best observers of the time ever since, and their results have tended more and more to show the communicability of the disease. The strides of microscopic pathology and the facts observed in regard to micro-organisms in other forms of disease have assisted in preparing scientific minds for the discovery that is under consideration to-day.

The importance of Koch's facts has led to an immense amount of work in the same direction for purposes of confirmation or refutation. It is now more than a year since his results were first given to the public, and a review of what has been done since then will be of interest and importance. No discussion of the individual papers will be attempted, and only those will be mentioned which have for their object the determination of the existence of the tubercle-bacillus and its significance.

Koch's results — after a long series of experiments, in which he not only discovered the organism which he claimed to be the actual cause of tuberculosis, but proved the assertion by the most careful cultivations and inoculations — are now so well known as to require little comment here.

Since the publication of his experiments, investigations have been carried on with a view to the discovery of the tubercle-bacillus in all the morbid processes known as tuberculous. In all of these experiments, the proportion of success to failure has seemed to grow larger as observers have become more familiar with the manipulation necessary for the demonstration of the bacillus. The few who have directly denied its existence in the tissue, or its pathological significance if there, have either seen reason to change their views or are still at work upon the problem. Before Koch there were other observers claiming the discovery of the specific cause of tuberculosis; thus: as the result of his work, Klebs⁴ had announced his monas tuberculosum, an actively-moving organism; Schüller⁵ and Toussaint⁶ a spherical micrococcus; and Aufrecht⁷ speaks of a rod-shaped organism, which he found in the centre of tuberculous masses, and which he now claims to be identical with Koch's bacillus.

From all of these Koch's discovery differs, in that it has no movement, is rod-shaped, and more than twice as long as it is broad, — being from one quarter to wholly as long as the diameter of a red blood corpuscle, — and in that he has isolated his discovery by culti-

vation and has produced the specific disease with the result, which none of the others have ever done.

Entering now upon the discussion of the papers that have been brought out by Koch's work, we come first upon that of Machiafara and Celli,¹ who published results showing that they had found the bacilli in fifteen cases of phthisis, — one with hæmoptysis and no physical signs, — and in the stools of phthisical patients in great numbers. They examined also, and with negative results in every examination, thirteen cases of other lung disease.

Formad,² after what he considers exhaustive research, grants that bacilli are present, but not invariably: he thinks that they may be the *causa mortis* by producing a fatal result in a process which would otherwise not be so, but he does not ascribe to this organism any quality which would make it a veritable *causa* or *materies morbi*.

Balmer and Fräntzel³ find the bacilli in enormous numbers in rapid cases of phthisis, and less numerous in the more chronic ones. "Infection fever" was always present in the cases in which bacilli were present in large numbers. They found bacilli very numerous in the tissue of tuberculous lung, in the walls of tuberculous ulcerations of the intestines, and in the pus of tuberculous joint affections. Their observations lead them to the following conclusions: They found the tubercle-bacillus in the sputum of one hundred and twenty cases of phthisis without exception. In the cases of lung disease not tuberculous tubercle-bacilli were never found. Therefore when they are found in the sputum we have a case of tuberculosis. On the other hand, when they are absent after repeated and careful examinations of the sputum, tuberculosis of the lung may be excluded. They consider that a perfect prognosis of a case may be given as the result of repeated examinations of the sputum extending over a period of weeks or even months. They also conclude that the most favorable soil for the growth of this bacillus is in the cheesy contents of a cavity rather than in its walls.

Hiller⁴ thinks it possible to formulate the dogma that "Initial hæmoptysis is a symptom of the infection of the lungs, standing in the relation of effect to cause."

Schmidt⁵ thought he had proved that the so-called tubercle-bacilli were fat crystals, because they disappeared if treated with ether. Hirschfelder⁶ has however shown that even after boiling the cover-glass in ether, and washing in fresh ether, the bacilli may be readily demonstrated by Ehrlich's method. Schmidt probably dissolved out the coloring matter, and has himself since come to a belief in the bacillus.

Ransome⁷ demonstrated the bacilli in the expired air of cases of undoubted phthisis.

An opponent of Koch's views on the specific nature of the tubercle-bacillus is Balogh,⁸ who says he has found bacilli in the marshes around Pesth, which are indistinguishable from the tubercle-bacillus. Inhalation experiments with these bacilli caused nodular growths in the lung in which the tubercle-bacillus was

found; and inoculation with scarlatinal urine and with bronchial sputum gave the same nodular growths. He took no measures — so far as reported — for the absolute exclusion of the tubercle-bacillus.

Professor Koryani⁹ found Koch's bacilli in the sputum of a case which had been regarded as one of pulmonary syphilis; by this means a correct diagnosis was reached.

Guttman¹⁰ has been unsuccessful in his researches, only finding the bacilli four times out of one hundred preparations of phthisical sputum, — all prepared after Ehrlich's method.

D'Espine¹¹ finds no correspondence between the number of the bacilli and the stage of the disease.

Lichtheim¹² has found bacilli in the sputum of patients with cough, before the lungs present any sign whatever. He considers, however, that the point of origin of inflammation must have some communication with the air passages before the bacilli can be discovered in the sputum, even in well-advanced tuberculosis. He found bacilli in the stools of intestinal tuberculosis, and especially in the ulcerations of the intestinal wall; he also found them in cases of tuberculous peritonitis.

Chiari¹³ thinks that the number of the bacilli is in direct proportion to the severity of the disease. He has never found any other bacilli staining as does Koch's.

Heron¹⁴ believes that the tubercle-bacillus furnishes a good prognostic guide, and that the more numerous it is the more rapidly fatal is the disease.

Smith¹⁵ demonstrated the tubercle-bacillus in the expired air of consumptives.

Pfeiffer,¹⁶ after a great number of observations, comes to the conclusion that the bacilli can always be found in the sputum of advanced tubercular disease of the lung, but that the examination must be repeated a great number of times before the definite exclusion of bacilli can be reached.

Babès,¹⁷ of Pesth, demonstrated the bacilli in the urine of three patients, in two of whom tuberculous nephritis with ulceration of the pelvis of the kidney was demonstrated afterwards in post-mortem examination; in one there was also tuberculous ulceration of the bladder.

Crämer¹⁸ and Menche¹⁹ both consider the tubercle-bacillus as a diagnostic landmark. Crämer, however, found an organism staining like the tubercle-bacillus in every case in twenty examinations of healthy stools. Menche claims that the examinations are liable to error because of imperfect staining; and, further, that possibly tuberculosis of the intestinal wall may be only manifest in the stools.

Fränkel²⁰ found numerous tubercle-bacilli in the pus of a scrofulous or tuberculous joint, and Dreschfeld²¹ confirms this by the same observation in a case of the same nature in the ankle. Fränkel has also found the

bacilli in the secretions covering laryngeal ulcers in fifteen out of sixteen cases. Lewin confirms this, but Guttman was unable to do so in two cases.

Ziehl¹ has obtained positive results in seventy-three cases of undoubted phthisis; he found no bacilli in thirty-four cases of other lung disease. He thinks it more likely that there is no other "fungous-form" in nature to be stained thus, than that the tubercle-bacillus is the only one which is stained slowly in fuchsine and methylene blue. He considers the observation of the bacillus a certain means of diagnosis of the tuberculous process and a method of differentiation from other forms of disease; but their absence must not be considered as excluding tuberculosis. He speaks with especial certainty upon the prognostic value of the numbers of the bacilli in the excretions.

Rosenstein² found the bacillus in the urine of a patient with symptoms of tuberculous disease of the epididymis, the lungs being perfectly free. Lichtheim detected the bacillus, post mortem, in the contents of the pelvis of the kidney in a case of renal tuberculosis.

West's³ conclusions, after the examination of fifty cases of phthisis, are: (1.) That bacilli are found in all cases of phthisis with excavations, varying in number with the rapidity of the destructive process. (2.) That their arrangement in groups and masses indicates a greater amount of destruction of the lung tissue, unless the isolated bacilli are in great numbers. (3.) That there is no variation in the size of the bacilli. (4.) That the bacillus being evidence of the destruction of lung tissue may be confirmatory diagnostic evidence, although he has only found them after the physical signs were clear.

Williams⁴ found bacilli in 106 out of 109 cases of phthisis. Of the remaining three, in one but one examination was made, in another the excretion seemed to be purely bronchial, and in the third the slides were spoiled and he could get no more. He considers it hardly justifiable to draw any conclusions from the activity of the disease and the number of the bacilli, although as a rule they are few in the cases in which the disease is quiescent.

Dreschfeld⁵ found bacilli in varying numbers in forty-six cases of positive lung tuberculosis, in two or three doubtful cases, and none in eight non-tuberculous lung affections. He considers them of diagnostic but not of prognostic value.

Dettweiler and Meissen,⁶ after the examination of eighty-seven cases of phthisis, conclude that the number of the bacilli in the sputum has no bearing upon the prognosis. An observation which they have confirmed by a series of parallel records, clinical and of the number of the bacilli in the sputum.

Spina⁷ asserts that there are other bacilli with the same staining reaction as the tubercle-bacillus, and that he can find no other means of differentiation; that he could not find Koch's bacillus in tuberculous organs that had not been for a certain time exposed to the air; and that Koch's results are inconclusive, on the ground of too few experiments.

Immediately after Spina's work was published,

Koch's⁸ reply to his critics appeared. His article is characterized by vigor and by an evident security in the position he took at the start upon the merits of his discovery.

He first turns his attention to America, and merely mentions Cutter,⁹ who considers the bacillus to be "embryonal forms of mycoderma aceti." Of Rollin Gregg,¹⁰ who suggests that the bacillus may be only fibrine filaments, Koch says he seems to have considered that microscopical investigations would be superfluous for the establishment of his views. Schmidt¹¹ is advised to get good colors and learn how to use them before announcing fat crystals as bacilli. Formad¹² is told to become sufficiently expert not to let his animals die of tuberculosis when inoculated with wood, glass, metal, etc. Sternberg's¹³ failure to find the bacillus puts him out of court.

Then, turning to Germany, he remarks that "if one thinks that Germany cannot bring forth such blossoms of tubercle literature as these he is much mistaken." He says that Beneke¹⁴ must have found fat crystals and not bacilli in the blood of healthy men; that Crämer's twenty cases of bacilli in the stools of healthy men have been contradicted by Menche¹⁵ and Gaffky's¹⁶ experiments, and that they were not identified with the tubercle-bacillus, although they were stained after Ehrlich's method. Balogh¹⁷ found bacilli in Berlin mud, which Koch did not succeed in doing. Koch, moreover, denies any value to Balogh's inoculation experiments, because no sufficient precautions for the exclusion of the tubercle-bacillus were taken. Schottelius¹⁸ produced anatomical tuberculosis in dogs by causing them to inhale masses of finely-pulverized non-tuberculous matter. Koch says that the anatomical appearances are not the criterion of what is tuberculous, and that Bertheau and Weigart have completely contradicted him. Dettweiler,⁶ discriminating between phthisis and general tuberculosis, attempts to show that the tubercle-bacillus is the accompaniment and not the cause of tuberculosis. Koch thinks he would change his mind if he knew more about the pathology of tuberculosis. Koch¹⁸ then turns his attention to Spina, and in summing up a criticism of his work — after leaving exposed the fallacy of his reasoning — concludes by saying: "All his work shows that Spina does not know enough to observe bacteria microscopically, nor to cultivate nor to inoculate them. His work will have no influence upon the discovery of the tubercle-bacillus."

Since Koch's article in March observations have been published by Demme,¹⁹ who thinks he can confirm Lichtheim's observations as to the bacilli in acute military tuberculosis. He considers it probable that ulceration is necessary before the bacilli can be seen in the excretions. As an instance of probable infection he relates the case of a child which was put out to nurse in a family, and whose foster-father died of acute phthisis. The child had not the slightest hereditary taint of phthisis or of syphilis, and was infected through

the nasal mucous membrane. After suffering from ulcerative ozæna it developed tubercular meningitis, and died. Tubercle-bacilli were found in the ulcerated and non-ulcerated pituitary membrane.

Purser¹ quotes a case in which the bacilli were discovered in the sputum five weeks before the clinical signs showed any disease of the lungs.

Prudden² found bacilli in forty-six out of fifty-eight cases in simple sputum preparations, and in thirty-nine out of forty-two of sections. He thinks it is evident that in nearly every case of tuberculosis there are many miliary tubercles of all forms, and in many cases much tuberculous tissue from which the bacilli seem to be entirely absent, which may perhaps be explained by their not staining well after life is gone or going, and perhaps by their having disappeared from tubercle which has come to a stand-still.

The longest and clearest work upon the subject of the tubercle-bacillus yet published is that by Mr. W. Watson Cheyne.³ As a preliminary to his work this gentleman visited the laboratories of Toussaint at Toulouse, and of Koch at Berlin, and observed the methods of work at both places, carrying away material for subsequent experiment and examination.

In his experiments as to the inoculability of tuberculosis he has exercised the greatest possible care to prevent contamination of instruments and hands, and has kept the animals experimented upon under the very best hygienic conditions, this latter a precaution that has not always been taken.

In his inoculation experiments with non-tuberculous material he obtained negative results in every case. He explains the contradictory results of former observers by, first, the mistaking of cheesy masses, not tubercular, for tubercle where a microscopic examination was not made; and, second, by the fact that even where a microscopic examination was made the accuracy of the diagnosis would depend very greatly upon the methods of staining employed, and the views which the observer held as to what constituted a tubercle. It must be remembered also with regard to the early experiments in this direction that the danger of mediate inoculation was not recognized, and that therefore the channels for the possible introduction of specific micro-organisms were left unguarded, as the precautions necessary for the thorough disinfection of instruments, etc., had not yet been made out. He failed to obtain tubercle with the material obtained from Toussaint, and explains the latter's results by the growth of tubercle-bacilli in his culture-fluids and their introduction during inoculation. The latter occurrence is rendered more probable because Toussaint trusts so much to disinfection by carbolic acid, which, although effectual against ordinary micro-organisms, has been shown to have no effect upon the spores of other bacilli unless it acts for a long time. The tubercle-bacillus apparently produces spores, and there is no reason to suppose that these are less resistant than those of bacillus anthracis and other bacilli.

In the researches of Klebs and Schüller a pure cultivation was not obtained, nor were the cultivations carried beyond the third generation; nor was Schüller always successful in producing tuberculosis by the injection of his cultivations. Not even the best microscopists and those who have done most with micro-

organisms (Koch, Weigert, etc.,) have been able to find the micrococci which Schüller declares he has seen in artificial tuberculosis. Cheyne has found micrococci only twice, and neither time in tubercle.

The difference between the results of previous researches and Koch's is that his are much the more definite. He, like others, cultivates micro-organisms from tubercle, but now it is no longer the fact that he only sometimes succeeds in causing tuberculosis, and that the tubercle thus produced occurs as slowly or more slowly than after the inoculation of tuberculous material. The result of the inoculation of his cultivations is certain, and more rapid in its commencement than after the inoculation of tuberculous matter.

As a result of all his work Cheyne comes decidedly to the conclusion that the tubercle-bacillus is the cause of tuberculosis, and that scrofulous glands, degenerated (strumous) synovial membranes of joints, phthisical lungs, in short, all those materials obtained from man, which, inoculated into animals, produce acute tuberculosis, contain in them bodies (bacilli) which, if they entered the circulation in sufficient numbers, would give rise to acute tuberculosis. It has been demonstrated by several observers that probably in all cases of acute tuberculosis a place can be found where these bacilli get into the circulation.

Cheyne considers the bacilli to be developed in the first instance in epithelioid cells, and that in the lung these cells are derived from the alveoli. He thinks that giant cells are epithelioid cells which have grown rapidly, apparently as the result of the presence of bacilli in them. He thinks that the structural definition of a tubercle must run as follows:—

"A nodule, composed of a central mass, consisting in the main of epithelioid cells, or in its place a cheesy mass, surrounded by more or less inflammatory tissue, with or without the presence of giant cells. The absolute diagnostic mark is the presence of the tubercle bacillus. It is not, however, always necessary for a tubercle to be a nodule. If there are plenty of epithelial cells or if it occurs when there are no pouches—as there are in the lung—it may be diffuse."

Cheyne then discusses the facts of the varying numbers of the bacilli in phthisis, and draws the conclusions that according to the number and rapidity of growth of the bacilli we have fibroid phthisis or caseous pneumonia. On this basis can also be explained the difference in the effects produced by these organisms in man and rodents. Rodents which are inoculated subcutaneously always develop general acute tuberculosis, which is extremely rare in man when compared with the frequency of pulmonary tubercle, because in man the bacilli are not inoculated, but are received into the bronchial tubes by inhalation; their entrance into the circulation is prevented in the first place by the inflammatory changes which occur around the alveoli in which the bacilli grow. If man were inoculated as rodents are analogy makes it probable that acute tuberculosis would be developed.

The papers which have appeared since this publication are few, but of great importance.

Ransome⁴ has shown bacilli exhaled by a patient suffering from phthisis. He obtained them by condensing the vapor of the breath in a large glass globe surrounded by ice and salt, and stained them by Gibbs's⁵ method.

Cornil¹ studied the bacillus in tuberculous granulations as being the most simple lesions. He found generally in the centre of a tuberculous mass a vessel obliterated by fibrine, and bacilli in the centre of this; they were usually present also in the walls of this vessel and near by in varying numbers. He found that the number and dissemination of the bacilli varies very greatly, and could not find them at all in one case of tubercular meningitis. He found them in the spaces between the epithelial cells (lymph spaces of Ranvier), and in the connective tissue, and in the protoplasm about the nuclei of the embryonal cells which form tubercle.

Ballagi² concludes from his investigations that (1) Koch's bacillus can be separated from other forms of bacilli. (2.) A differential diagnosis from all other organisms can be reached by their staining reaction (Ehrlich's), and they can be thus separated in the tissue from putrefactive and disease germs (as the bacillus of leprosy). (3.) Putrefactive and other bacteria cannot be isolated by any known special staining method. (4.) The tubercle-bacilli do not occur with regularity in the sputum of persons in the first stages of phthisis (apex catarrh, hæmoptysis). (5.) In the sputum from patients in the advanced or fibroid stages the bacilli can always be found, especially in the form known as galloping consumption, although in no case do their numbers correspond invariably with the height of the fever or the stage of the destructive process. (6.) The tubercle-bacilli can be found in tuberculous organs when the process is not very old (*chronisch*). (7.) There are no bacilli in the sputum of non-phthisical patients. (8.) Their repeated occurrence is conclusive of the diagnosis. Their absence, however, does not prove the absence of a tuberculous process. (9.) Their number and distribution is of no prognostic value.

Fränzel³ has now observed three hundred and eighty cases of phthisis, and followed them up for months. He has examined also eighty cases of other lung disease, and always with negative results. In every one of the cases of phthisis he found bacilli in the sputum, and was often able to make a diagnosis by their presence, when the physical signs were negative — a diagnosis which was invariably confirmed by the further progress of the disease. In five cases which progressed with the picture of phthisis, no tubercle-bacilli were found, and further observation showed that none of them were cases of "cheesy infectious phthisis" (which was confirmed in three by post-mortem examination.) These further observations lead him to adhere to the first of the three laws which he enunciated in his former article, that the presence of the bacillus in the sputum determines the presence of tuberculosis. He also considers the quantity of bacilli — as determined after repeated examinations extending over a long time — as of great prognostic value. (He thinks that the examination should be extended over weeks or months, and should be repeated every day, or at least every second day, — with notes and comparisons, and the conclusions to be drawn from the general average.) He thinks that such a long series of observations will give us a more certain prognosis than even the physical signs. As a result of his further study of the subject, he wishes to modify slightly his second law, that is, "that wherever, after repeated

and careful examinations, no bacilli are found in the sputum there is no tuberculosis of the lung." This law would now read as follows: "When, after repeated and careful examinations no bacilli are found, — provided that sputum is present and comes from the lungs, — there is either no lung tuberculosis or else there are no cheesy softened foci emptying their contents into the bronchi."

(To be concluded.)

PHLYCTENULAR DISEASE OF THE EYES.⁴

BY OLIVER F. WADSWORTH, M. D., BOSTON.

THE affection to which I desire to call your attention to-day is characterized by the eruption of vesicles or pustules on the conjunctiva or cornea, and often attended by much apparent photophobia. It is one with which you are doubtless all more or less familiar under some of the many names given to it. Phlyctenular, pustular, scrofulous, lymphatic ophthalmia, conjunctivitis or keratitis; herpes or eczema of conjunctiva or cornea; fascicular keratitis; ulcer of the cornea, — such are some of the designations it has received.

The extended statistics collected by Cohn show that affections of the conjunctiva and cornea make up half the sum of eye diseases. Horner found the same to be true as regards children alone, with this difference, that whereas when all ages are considered, the conjunctival affections out-number much those of the cornea, with children the proportion is reversed; in them the cornea being implicated in 27.2 per cent., the conjunctiva in 21.7 per cent. of all cases. Moreover, according to Horner, phlyctenular conjunctivitis and keratitis comprise more than half of the disease of these membranes in the child. Arlt also says this is without question the most frequent of inflammations of the eye.

The very frequency of its occurrence makes its discussion appropriate before an assemblage of general practitioners. But its frequency is by no means the greatest of its claims to our interest. Its habitual obstinacy; its tendency to relapse or recur on the least provocation; the variations in form which it manifests; the fact that its appearance is of itself alone evidence, almost invariably, if not wholly without exception, of some deterioration or imperfection of the general health; and, finally, the frequent permanent impairment and occasional destruction of sight that it causes, are sufficient reasons for its careful consideration and study. According to Birch-Hirschfeld, six per cent. of the inmates of the blind asylums of Saxony lost their sight from this disease. Such a percentage is undoubtedly higher than would be found in this country. The number made blind by it bears, however, but a small proportion to the number of those whose sight, in one or both eyes, is more or less seriously and irretrievably injured.

While the vast majority of those afflicted are young children, adults are not wholly exempt, though with them the disease is comparatively rare. In my experience, also, the course is usually mild in adults, even if sometimes prolonged. It is in children chiefly that severe forms are seen and disastrous effects produced.

Unfortunately, by the laity the malady is very gen-

⁴ Read at the Annual Meeting of the Massachusetts Medical Society, June 12, 1883, and recommended for publication by the Society.

erally looked upon as a troublesome but innocent accompaniment of teething, safe to take care of itself, and to pass away so soon as the irritation attendant on dentition has subsided, or as a sequela of measles or other exanthem, not specially requiring treatment. In consequence of this opinion the child is only too often made the subject of experiment with "household remedies," or allowed, even aided, to aggravate the disorder by following its own inclinations.

For the physician the understanding of the affection is made somewhat more difficult than need be by the prevailing habit in text-books of treating of eye diseases according to their anatomical situation. There is justification for this method of division, but as a result of it diseases of the conjunctiva and of the cornea are separated more or less widely, and where, as in the present instance, the disease is essentially the same whether its habitat be conjunctiva or cornea, the identity does not always appear with sufficient clearness. Other reasons for confusion are to be found in the multiplicity of titles, some of them implying a relationship with other diseases which does not exist, and in the fact that by some authors certain variations of the disease have been described under different names and as if distinct affections, by others different affections have been grouped under the same name.

The term herpes applied here is a misnomer. There is no evidence that the eruption has any such special connection with the sensitive nerves as is the case with herpes generally; the lesion of the cornea which may accompany herpes zoster is quite other in character than the phlyctenulæ, and the same is, usually at least, true when corneal or conjunctival affection is coincident with the ordinary herpes febrilis.

Eczema, on the other hand, is a frequent accompaniment of phlyctenulæ, as it is also a common affliction of young children. But a considerable proportion of the eczema observed in this connection is a secondary condition, due to irritation of the skin by overflow of tears and rubbing, or, on the lip and alæ nasi, by the catarrhal flow from the nostrils often present at the same time. The ocular changes do, indeed, resemble in some degree those found in eczema, yet there seem hardly grounds enough for adopting the title of eczema of the conjunctiva and cornea which Horner has proposed.

The main characteristic of the disease is the eruption of vesicles or pustules; these may be single or multiple, may vary in size from that of the head of a small pin to a diameter of several millimetres; the process may be exhausted with the eruption of one phlyctenula, or successive crops appear at irregular intervals; they may be situated on the conjunctiva, or cornea, or both, either successively or simultaneously, or may extend from one to the other. The duration of the individual efflorescence depends in the main upon its size and its situation; on the cornea the course is slower than on the vascular conjunctiva. The amount of irritation is far from being in definite relation to the severity or danger of the disease.

On the conjunctiva the eruption develops almost invariably in the near neighborhood of the cornea, and shows itself in two forms, the typical cases of which are sufficiently distinct in appearance. The more common is that of an isolated efflorescence. Beginning as a localized, elevated congestion, the centre soon becomes grayish-white or with a tinge of yellow, due to an agglomeration of lymphoid cells. The epithelial

surface is thrown off, the mass of cells beneath escapes, and there is left a depression with raised edges, which gradually flattens and is again covered by epithelium, while the congestion fades. Around the pustule both conjunctival and sub-conjunctival vessels partake in the congestion; toward the fornix, where the conjunctiva passes from globe to lid, the conjunctival congestion extends, diminishing in amount, but often increasing in breadth as it recedes from the focus of inflammation, so that the whole congested region assumes a fan shape.

Comparatively seldom, however, does the patient present himself with this typical form of congestion. Oftener, other pustules appear in various positions, simultaneously or before the first has healed, and the congested area thus becomes a wide one, with reddening of the lid conjunctiva also. If the individual pustule is small and superficial it may run through its whole course in a very few days. From this there is every gradation to the sluggish, somewhat deep ulceration, three or four millimetres in diameter, its base ragged, grayish, infiltrated, which may be a fortnight in healing over.

The other, less frequent, type consists in the almost simultaneous development of small, often very minute, phlyctenulæ, studded along a part or the whole of the limbus conjunctivæ, close to the corneal border. The attending congestion is more general, though greatest in intensity here also at the site of the eruption. The duration of the individual phlyctenulæ is short, but successive crops follow each other more or less rapidly, and extend the time indefinitely. Both forms begin with a sensation of burning or smarting as of a foreign body, more marked in the latter variety.

So long as the affection is confined to the conjunctiva alone the subjective symptoms are comparatively light, and the prognosis is positively favorable, even if the course be somewhat prolonged. Yet, until convalescence is fully established, the danger that the cornea too may be implicated is always threatening, and when that occurs the situation becomes more serious.

The manner in which the cornea becomes involved varies. A pustule may fall astride of the corneal edge, half in conjunctiva and half in cornea. Should the pustule be small it will generally heal readily and do no damage, but a large pustule in this position may give rise to a deep, funnel-shaped ulcer and to infiltration of the cornea beyond it. It is not so very uncommon for such an ulcer to extend in depth and cause perforation. The so-called fascicular keratitis commences as a pustule in this position. Here, instead of following the normal course, the infiltrated raised edge of the ulcer is pushed farther and farther into the cornea, the tissue breaking down and leaving a groove in the corneal substance behind it. At the same time a bundle of new-formed vessels extends from the conjunctiva, keeping pace in its growth with the progress of the infiltration, filling, or more than filling, the groove, while only a scarcely perceptible depression separates its corneal extremity from the gray, crescentic wall which precedes it. Usually the infiltration moves at first toward the centre of the cornea, but it generally swerves a little from a straight line. It may stop at any part of its course, or cross nearly to the conjunctiva on the opposite side. It never perforates, but the vessels disappear when the process is at an end, leaving a grayish cicatrix which is exceedingly persistent and characteristic.

Different again is the behavior where there are numerous small phlyctenulæ along the edge of the cornea, in the limbus. Then, if the condition persist some time, vesicle following vesicle, the irritation excites the growth of vessels from the edge into the cornea close beneath the epithelium. The progress of the vessels depends on the degree of the inflammation at the site of the efflorescence, and they extend farther where this is greatest, but the regularity with which a fringe of straight vessels is formed along the whole circumference of the cornea is sometimes very striking. With the subsidence of the inflammation in the limbus the corneal vascularity vanishes without leaving a trace. More than a superficial ulceration of the cornea, hardly extending deeper than the epithelial layer, I have never seen with this form, but an infiltration, leading to annular ulceration of serious amount, is described as a very rare complication.

If the cornea is affected independently the pustules show the same variation in their behavior as on the conjunctiva. There is the same difference in size and number, the same irregularity in the time of their successive appearance and in their duration. They may present themselves at any part without distinction. There seems to be no place of least resistance. Congestion about the pustule is, of course, wanting, but there is circumcorneal congestion, chiefly on the side nearest the inflammatory focus, and fading toward the fornix. A small pustule may be absorbed without coming to ulceration, but this is uncommon. From the superficial, grayish, subepithelial swelling, which, losing its covering, readily heals without leaving any sign, there is every degree to the extensive, deep, yellowish infiltration, causing deep destruction of the corneal tissue, even perforation, healing slowly, generally with the assistance of vessels growing out from the conjunctiva to its edge, and only by the formation of permanent cicatricial tissue. Through this tendency to the formation of vessels on the cornea there is sometimes, when the eruption has been repeated and long continued, a sort of pannus developed. Such a pannus mostly may be distinguished by the greater irregularity of its form and distribution from trachomatous pannus, which latter almost always starts from above, while its lower edge is approximately horizontal. Seldom, indeed, a sluggish, deep infiltration is complicated by hypopion and a low form of iritis. When it is borne in mind that, besides all the variations that have been indicated, a catarrhal conjunctivitis, with even considerable swelling of the membrane and mucous secretion, may be superadded, the possible diversity in the appearances presented is manifest.

The degree of injury to the eye as an organ of vision depends chiefly upon the situation of the lesion; a considerable opacity near the circumference of the cornea may be of little moment in this respect, yet without directly interfering with the entrance of light to the pupil it may still do harm by changing the proper curve of the cornea. The growth of vessels toward the ulceration is always a welcome manifestation, since the reparative process is hastened by their means, and it may be said in general that the perfection of recovery, the eventual freedom from opacity and changes of curvature, is the greater the nearer the ulcer is to the circumference and the shorter the time till healing is accomplished.

Of the subjective symptoms the most prominent and most troublesome is usually photophobia, so called.

With an isolated eruption on the conjunctiva or a single pustule on the cornea this symptom may be but little pronounced. As a rule, however, it is present, and especially if the efflorescences are numerous and repeated does it often reach such a degree as of itself to become almost a distinguishing characteristic of the disease. A child thus affected may never open its eyes even in a moderate light for days or weeks; it buries its head in its hands, in the pillow, or in the clothes of its attendant, resisting violently any attempt to turn its face toward the light. It seems sometimes as if there were an effort to drag all the features, forehead, cheeks, lips, to one common centre and heap them up over the eyes. To some extent in accord with the amount of the photophobia is the quantity of watery secretion poured out, which, by keeping the lids continually moistened, causes excoriations and increases the irritation. Yet it would be a mistake to suppose that the severity of the ocular affection is to be accurately gauged by the photophobia. Rarely, indeed, where this is pronounced, is the conjunctiva alone involved; there may, however, be but few pustules on the cornea and those small and near the periphery. Precisely the worst cases, those with large, sluggish infiltration, extending deeply and causing large loss of substance (dense permanent cicatrices), or perforation with its consequences, have this symptom usually but little marked.

The title scrofulous ophthalmia, though it affirms too much, yet indicates rightly the general direction in which the cause of the disease is to be sought. Not that all individuals afflicted are scrofulous, even when the most extended application is allowed to the term; many are so, and it is in such that the most serious and persistent cases are to be found, notably the sluggish form, as well as those with great blepharospasm. But a condition of health below the norm, which carries with it an impaired power of resistance to harmful influences, is always present. Exposure to rapid changes of temperature while imperfectly protected by clothing, followed by the onset or exacerbation of catarrhal inflammation of the mucous membrane of the nasal passages and fauces, too often coincides with the beginning or increase of the ocular symptoms to be denied an influence as a causative factor. The exanthemata—measles, scarlet fever—may be regarded as acting to depress the tone of the general system, while the congestion of the mucous membranes they cause, in which the conjunctiva shares, may well prepare the ground in some measure for the local affection.

To form a definite diagnosis we must obtain a view of the eye. In many cases this presents no special difficulty, in others the ingenuity and patience of the physician are taxed to the utmost if he wishes to avoid the use of forcible measures, and often in vain. If the child can be coaxed to open its eyes, this is, of course, preferable; occasionally the application of cold to the lids will relieve, temporarily at least, somewhat obstinate spasm. Yet whatever means are employed they will fail in many instances, and then the only resource is the elevator of Desmarres, the child being placed on its back, and its head fixed between the knees of the operator. The use of the fingers to raise the lids in such case can never be as effective, and must produce painful and sometimes dangerous pressure on the eye.

Inspection of the eye is also necessary for the formation of our prognosis. Hesitation or mistake as to this

may forfeit the confidence of the parents, a confidence often tried at the best by the persistency of the disease, and without which careful attention to the details of the treatment is scarcely to be expected. It is not to be forgotten, however, that only a provisional prognosis can be given from the condition at the moment, and the state of the general health is always to be taken into account. Although the central portion of the cornea may have escaped hitherto, no one can safely predict that it will not be affected later. Moreover, we do well to warn the parents before dismissing the case from treatment that, for several years, with any depreciation of the general health, the disease may reappear.

The treatment may be divided into general and local. What has been said of the ætiology indicates both the importance and direction of the general treatment. It should never be neglected even in the lightest cases. The diet should be easily digestible and nourishing, and attention to it in detail is always advisable; healthy action of the skin is to be promoted by frequent bathing; iron, malt, and cod-liver oil to be prescribed according to the case. The advantage of fresh air and light can hardly be overestimated. Even in the coldest weather it is usually better that the patient, properly clothed, should be taken out for a time daily, and this is the more needed the poorer are the hygienic surroundings at home.

Blepharospasm, so-called photophobia, is to be feared, not for itself, but for the prejudicial consequences it entails. The violent action of the orbicularis irritates still farther the already inflamed cornea, incites to friction and consequent excoriation of the skin of the lids with the result to increase the general nervous excitability, and prevents the free bodily movement so necessary, in children especially, for the preservation of health. In considering the means for its relief, we should constantly remember that the stimulus that excites it starts from the irritated terminations of the trigeminus, not from any hyperæsthesia of the retina. The indication then is to relieve the abnormal sensibility of these terminations. It is the irritation of the corneal nerves that chiefly excites the blepharospasm, and so far as they are concerned the local narcotic effect of atropine makes this our most reliable agent. The alleviating effect of even the first application is sometimes very great. A two-grain solution may be employed every other day, or two or three times daily, and if the case is seen early the spasm may thus be kept within bounds. But should the photophobic habit, if I may be allowed the expression, be once firmly established, relief is more difficult. When the lids are persistently kept closed it is commonly useless, or worse than useless, to intrust the application of this or any collyrium to the parents or attendants. In the efforts to force open the lids of a struggling child with the fingers, more harm is likely to be done than the atropine will counteract, and the increased flow of tears excited by the struggle will rapidly remove the small amount that has been instilled. The elevator is hardly safe in untrained hands. The application may, perhaps, be made when the child sleeps, but otherwise in such cases it is better left to the physician. Sometimes, however, reliance must be chiefly placed on less direct treatment. The benefit of cold applied to the lids has already been referred to. All friction of the lids must be prevented. Excoriations of the skin about the eyes may be washed with a solution of silver nitrate, or an ointment, containing ten grains of zinc oxide, or three or four grains each

of zinc oxide and white precipitate to the drachm, be applied. The same treatment may be employed for eczema of the upper lip and *alæ nasi*, or elsewhere about the face, if present. Irritants are harmful. Darkness only aggravates the symptom. Within doors the light should be moderate and even, and be increased as the condition improves, but sudden changes of light, producing, as they do even in a state of health, contraction of the orbicularis, are to be carefully avoided. In the open air a dark shade, large enough to protect both eyes, though only one be affected, and arranged to stand out free from them, with a veil or smoke-glasses if required, are of use. It is by attention to details that success is to be attained.

When the eruption is limited to the conjunctiva a simple collyrium of borax in water or camphor water is often all the local treatment needed. Calomel, dusted lightly upon the conjunctiva from a camel's hair pencil, every day or two, till congestion has disappeared, seems to have a good effect in preventing relapses. But it must be employed with precaution. It should be pure and dry, only a very thin film of it should be formed on the conjunctiva, and the lower fold should be inspected after a moment or two, that if any have collected there in a clump or thread it may be removed. The action of calomel was for a long time unknown; now it has been demonstrated that it is soluble, to a slight extent, in salt water, and it probably acts as a weak solution of bichloride. In the presence of iodine there is produced a biniodide of mercury, and it should, therefore, never be used when the patient is taking any preparation of iodine, else a troublesome eschar may be the result. Properly used it is painless, and I have myself never seen any ill effect from it.

In general, astringents are to be avoided, but when the condition is complicated with a catarrhal inflammation of the conjunctiva, mild collyria of alum, zinc, or silver nitrate are in place. Yet these should be employed cautiously and their action watched if any fresh eruption exists.

With an eruption on the cornea I rely, with most oculists, on the action of atropine. Its soothing influence has already been alluded to. The frequency of its application is to be governed in the main by its effect on the pupil, and it is to be continued till the ulceration is again covered by epithelium. Here, also, calomel is apparently of benefit, but is, in contradistinction to the conjunctival affection, only to be applied after epithelial regeneration is well under way. Yet I would make one exception to this last statement. In the fascicular form of keratitis it has seemed to me that calomel, applied somewhat freely during the progress of the band across the cornea, has sometimes checked its course. So erratic, however, is this variety, and the opportunity for studying it so comparatively infrequent, that I am willing to admit it may have been coincidence rather than effect that I observed. With the ointment of yellow oxide of mercury, much used in the same conditions as is calomel, my experience has been limited, and it has appeared to me at least less agreeable to the patient.

The sluggish, deep infiltration, whether at the edge of the cornea or more central, showing little or no tendency to the formation of vessels, demands, besides atropine, the application of hot fomentations, continued half an hour or an hour three or four times daily. These help to relieve the pain, sometimes considerable,

and invite the vascular outgrowth from the conjunctiva needed to furnish material for repair. Should perforation occur, pain usually ceases as by magic, and the reparative process begins. The subsequent care after perforation does not differ from that required in similar circumstances arising from other cause.

Many and various have been the remedies recommended to promote the absorption of corneal opacities left by this or other diseases. My own belief is that none of them are of special value, and that the opacities are best intrusted to nature to reduce, as she certainly will in part. Our task, after the immediate attack has passed, is to see to it that measures to improve and preserve the general health are continuously carried out and thus recurrence prevented.

RECENT PROGRESS IN DISEASES OF CHILDREN.

BY T. M. ROTCH, M. D.

ASTHMA DYSPLEPTICUM.¹

DR. OSKAR SILBERMANN, of Breslau, first published, in 1876, an article on the so-called dyspeptic asthma of children, and at the same time mentioned the reflex phenomena experimentally shown by Mayer and Privram to be produced by irritation of the stomach. Silbermann has lately had three more cases, which he reports as follows: (1.) A boy, thirteen months old, breast fed until the eleventh month, and always healthy, excepting that he had lately, for a short time, had diarrhoea, was seized with vomiting, great dyspnoea, the respirations being 70, and very rough, cyanosis of the face, pulse 160, small in character, cool extremities, and an anxious expression of face, apparently as if he was about to expire. The temperature was 37.6° C. The epigastrium was somewhat distended, and tender on pressure. Remedies for dyspepsia were given, and the child was perfectly well in two days. (2.) A girl, six months old, was taken sick with gastric symptoms, was very cyanotic, respirations 60 in the minute, pulse small, 120, temperature 36.9° C., repeated vomiting. Perfect recovery on the following day. (3.) A girl, eight years old, was seized with dyspeptic symptoms, and had a small, irregular pulse of 160; the epigastric region was distended and sensitive, the respirations were 28; twelve hours later the respirations were 60, and harsh in character; there was a high degree of dyspnoea, and great cyanosis; temperature 37.1° C. She recovered completely some hours afterwards.

The reflex gastric symptoms of slow pulse and increased blood pressure, experimentally produced by Mayer and Privram, are not altogether similar to the appearances observed in asthma dyspepticum. Traube and Henock supposed that a reflex irritation starting from the stomach caused a vaso-motor contraction in the arterioles, thus causing coldness of the extremities, weak pulse, and all the other appearances. Silbermann interprets the phenomena as primarily a paralysis of the vagus filaments, from which is developed a retarded action of the left ventricle with overfilling of the pulmonary circulation and the right heart, and secondarily overloading of the blood with carbonic acid, and the consequent dyspnoea and oedema of the lungs.

¹ Berlin. klin. Wochen., 23, 1882.

GROWTH AND WEIGHT OF INFANTS.²

Dr. Emil Pfeiffer, of Wiesbaden, has investigated the subject of infantile growth in reference especially to the figures of Fleischmann representing the increase in weight during the first year. Fleischmann's observations having led him to announce the rule that the average weight of sucklings at the end of their fifth month is equal to 550 grammes more than double their weight at birth, and at the end of the first year 900 grammes less than three times their birth weight; he has from this formula deduced a line, or, rather, curve of growth, by which he determines whether any individual infant is normal or abnormal in development. Pfeiffer, although as yet he has not established any rule of his own, warns us that Fleischmann's deductions are probably unsound both in actual figures and on physiological principles, and considers that Fleischmann's results have already been greatly modified by the growth curves collected by Mech, and that the figures of Bouchaud are more correct, although more complicated, Fleischmann's formula being especially noticeable for its simplicity.

Pfeiffer illustrates the practical weakness of the Fleischmann formula by two cases: (1.) An infant, weighing at birth 5000 grammes, was found at the end of the twenty-second week to weigh 9100 grammes, which was much less than the 550 grammes more than double his initial weight. This same infant when one year and ten days old weighed 12,790 grammes, which again was far more than the 900 grammes less of the formula, and yet no one could say that this child was poorly developed, for at the end of its first year it weighed 25 pounds, had its eight incisors and four molars, and was strong and well. (2.) A female infant, born in the thirty-third week, with a birth weight of 2225 grammes, weighed at the end of the twenty-second week 5125 grammes, which was 675 grammes rather than the 550 grammes of the formula, while at the end of the first year it weighed 8430 grammes, which was 1755 grammes more than three times the original weight rather than the 900 grammes less of the formula, yet this infant was not very strong, and in fact was considered rather small and weakly.

The Fleischmann formula would have made the first infant attain the enormous weight of 14,100 grammes at the end of its first year, while the second infant would have weighed only 5575 grammes, the usual weight of an infant three and a half months old. Pfeiffer considers that much more reliable results can be obtained by reckoning from the absolute amount of increase without regard to the initial weight, and from a growth curve constructed in this manner, estimating the deviations from the normal average weight which may arise in any individual instance. This method, already adopted by Vierordt and Bouchaud, is nearer perfection for the general run of cases in that it is also sufficient for determining the weight of both very heavy and very light children. Pfeiffer then states that from his observations on nursing women he has found that during the first five months the secretion of milk amounts to not, or if any, very little over 1000 to 1100 grammes a day, and that these figures representing the total amount which the child can get from the breast, the simply breast-fed child, whether heavy or light, takes the same amount of nourishment during these first five months. It is therefore clear that the

² Jahrbuch. für Kinderheilk., Band xix., Heft 2.

very large child cannot increase in weight more than the child of medium weight, and that its increase is not proportional to its initial weight, but to the amount of nourishment which it imbibes. Small, puny infants may possibly not take the whole amount of nourishment provided for them. On the other hand the case is altered in the second half of the first year, a time when breast-fed children are frequently given some additional food, for now the larger and probably stronger infant will usually take a larger amount of food than the smaller infant, and will thus have a greater opportunity for gaining in weight, and this fact will make the increase in the second half of the first year greater than Fleischmann allows for, and thus prove to be a disturbing element in his formula. Pfeiffer has obtained the following results from a number of children with widely different initial weights, and all of them fed on the breast during the first five months, and later with cow's milk and other food in connection with the breast milk. The average weight for each month has been reckoned, and at the same time it was found that the average initial weight was 3416 grammes:—

Month.	Monthly Increase.	Increase from Birth to end of First Month.	Weight at end of First Month.
1	875	875	8791
2	886	1261	4677
3	754	2015	5481
4	748	2758	6174
5	598	3359	6772
6	902	3958	7874
7	477	4435	7851
8	591	5028	8442
9	557	5580	9096
10	576	6256	9672
11	315	6571	9987
12	217	6788	12,004

A curve constructed from these figures is almost identical with that of Bouchaud.

PROPORTION OF THE BLOOD CORPUSCLES IN MEASLES.¹

Prof. R. Demme has made some observations on the increase and decrease of the red corpuscles of the blood in twenty cases of measles, and the relation between the red and white corpuscles. He found that occasionally in the beginning of the fever stage there was a slight increase of the red corpuscles, while on the development of the eruption there was a decrease which lasted for twelve or forty-eight hours after the fever, so that the red corpuscles sank to half the normal number. After eight or ten days the number gradually increased with frequent variations. The spectroscope showed in the beginning an increase, and after the appearance of the eruption a decrease of the hæmoglobine. The decrease of the red blood corpuscles occurred also in a case of measles where there was an intense efflorescence, but no fever. An absolute increase of the white blood corpuscles was found in the course of the disease during the fever stage, and usually before its decline.

THYROID GLAND IN MEASLES.

In a number of cases there was an acute swelling of the thyroid gland, which retrograded spontaneously in ten cases, but in twelve cases was intractable until iodine was used. These swellings lasted in their acute

¹ Jahrbuch. für Kinderheilk., Band xix., Heft 2.

stage for from one and a half to three days, caused marked dyspnoea, and usually disappeared quickly. In one case there was an abscess formation, which on being opened was found to contain pus which was full of rod bacteria and micrococci. In this case the whole right lobe of the thyroid came away, but recovery took place.

GALL-STONES IN AN INFANT.²

Dr. A. D. Walker reports the case of an infant three months old, and healthy, who when it was one month old had an attack of icterus, and who, after some hours of restlessness and suffering, passed by the rectum, a purgative having been given, three gall-stones, the largest of which weighed two grammes.

HYDATID OF LIVER.³

Dr. A. M. Edge reports the case of a child four years old, and previously healthy, who while playing with another child was observed to complain of abdominal pain when his playfellow grasped him around the waist and lifted him up. On examination a fluctuating tumor was found as large as a small orange in the epigastrium, a little to the right of the median line, apparently attached to the liver, which was not enlarged. In a few weeks the tumor increased in size and became superficial so that a puncture was easily made, and thirteen drachms of clear liquid rich in chlorides was withdrawn; no hooklets were found. After the puncture the cyst entirely disappeared.

STERCORACEOUS VOMITING.⁴

Professor Rosenstein reports a remarkable case of faecal vomiting in a boy nine years of age. The child during a period of five weeks, from time to time, was attacked with spasmodic abdominal pains and loss of consciousness, the attack ending with the expulsion of faecal masses from the mouth. Between the attacks the child was apparently perfectly well. The scybala varied from one to three centimetres in length, and at times were still larger. Enemata caused a discharge from the mouth as well as the rectum. This faecal vomiting usually followed a severe attack of pain, but sometimes also occurred without pain, and there was generally though not always an accompanying rectal discharge. The attacks by degrees grew less frequent under the administration of enemata and large doses of bromide of potash. Professor Rosenstein supposed that under the influence of a neurosis which caused a kind of tetanus a temporary stricture was produced in the intestine, and from this point an upward and downward peristalsis took place.

SUDDEN DEATH IN INFANTS.⁵

M. F. Bontemps has written quite a valuable article on the various lesions which may cause sudden death in infants, his observations having been made principally at the morgue under the direction of Professor Brouardel, who holds the chair of Legal Medicine in the Faculty of Medicine in Paris. The author points out the fact that very little has been written on this subject, only one class of cases having been touched upon by Pibar-Dufeillay in 1861, in an article entitled *Etude sur la Mort Subite chez les Jeunes Enfants*, causée par

² British Med. Jour., 1112.

³ Lancet, ii., 18, 1881.

⁴ Berlin. klin. Wochens., 34, 1882.

⁵ De la Mort Subite chez les Jeunes Enfants. Thèse par M. F. Bontemps. 1882.

les Troubles du Système Nerveux. In speaking of sudden death the author states that he means those cases where there is a sudden cessation of life without mechanical or toxic influences in an apparently perfectly healthy child, or one whose disease shows no signs of an immediately fatal result. As to the frequency of sudden death at different ages M. Devergie out of forty cases found none to be infants; M. Tourdes out of eighty cases records four infants, the youngest of which was seven months; Dr. West found that out of 627 sudden deaths registered in 1854, 236 were under one year, and 36 were from one to five years old. The cases referred to by Bontemps were all under two years, and he divides the subject into four classes: I. Sudden death connected with the nervous system. II. Sudden death connected with the respiratory system. III. Sudden death connected with the circulatory system. IV. Sudden death connected with the abdominal organs. In Class I. cerebral congestion is first spoken of, the author claiming that as a cause it is seldom found, but as a frequent result from some other primary cause, such as spasm of the glottis. Passing shortly over cerebral anæmia, meningeal hæmorrhage is next referred to as being excessively rare, only one case being known of, that reported by Valleix, and in that other important lesions were also found at the autopsy. Cerebral hæmorrhage was rare, two cases only having been found, one, a puny child, dying in five minutes, and one, a healthy infant of three months, dying in half an hour, there being sudden convulsions in both cases.

A certain number of cases take place in epidemic cerebro-spinal meningitis; M. Tourdes has seen several infants die in a few hours of this disease, and cites one instance where an infant six weeks old died so quickly that it was supposed to have been poisoned with laudanum, but the autopsy showed characteristic pathological changes at the base of the brain and the upper part of the cord. Tubercular meningitis was found as a cause in several cases, that of M. Rohrer being especially noticeable, where a little girl was attacked in the middle of the day with violent headache and died in the evening in convulsions. Hydrocephalus and cerebral tumors are instanced as causes. Simple eclampsia from reflex causes were found to have proved fatal in a number of cases. Six interesting cases of sudden death from spasm of the glottis are reported. The author next speaks of sudden death connected with diseases of the respiratory system, and after referring to laryngitis stridulus as affording examples, reports sudden death in two cases of pleuritis where an autopsy was obtained. Two cases of tuberculosis of the lungs, with autopsy, are next reported. A number of interesting cases of sudden death occurring in the course of bronchitis suffocativa are recorded, and nine cases of death taking place in a few minutes during the spasm of pertussis.

In Class III., where sudden death connected with the circulatory system is spoken of, a number of sudden deaths from syncope are first referred to, and then deaths during endocarditis, pericarditis, and malformation of the heart. The author concludes his thesis with a description of a number of sudden deaths connected with the abdominal organs, especially from typhoid fever, intestinal parasites, peritonitis, and cholera infantum; also the following interesting case of hæmatemesis: An infant born at full term, of healthy parents, and apparently strong and vigorous,

vomited a considerable amount of blood twenty hours after birth, and suddenly died; the autopsy presented a number of ulcerations at the cardiac end of the stomach. Three cases from renal disease are also described, with the accompanying autopsies.

This thesis of Monsieur Bontemps is well worth the notice of the general practitioner, if it is only to direct his attention to the fact that in the very diseases which he has been in the habit of treating for years without the accident of sudden death arising, he is at any time liable to meet such a case and must be prepared for it.

Reports of Societies.

THE NINETEENTH ANNUAL MEETING OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY.

THE nineteenth annual meeting of the American Ophthalmological Society was held at the Kaaterskill House, Kaaterskill, on July 17th and 18th. Three long sessions were held, and many papers read before the Society and discussed. The meeting was called to order by the president, DR. H. D. NOYES, of New York. After reading of the records and reports by the secretary, DR. R. H. DERBY, of New York, and the appointment of committees, the Society proceeded at once to the consideration of the papers presented.

The first paper read was one by DR. H. DERBY, of Boston, on the

RESULTS OF THE EXAMINATION OF THE REFRACTION OF FOUR CONSECUTIVE CLASSES AT AMHERST COLLEGE.

The entire number entering and graduating were examined, but for the purposes of the paper only such were considered as completed the entire course. The results may be summarized as follows: Average age at entrance nineteen years; average age at graduation twenty-three years.

	Refraction at Entrance.	At Graduation.
Manifest hypermetropia	89	47
Myopia	90	120
Emmetropia	125	87
	254	254

The myopia in 32 cases remained stationary. In 58 cases the myopia increased.

Average myopia at entrance 1.8 dioptic.

Average myopia at graduation 2.4 dioptic.

Average increase 0.6 dioptic.

Of the 125 emmetropic cases at entrance 86, or 68.8 per cent., remained emmetropic.

Ten, or 8 per cent., developed manifest hypermetropia.

Twenty-nine, or 23.2 per cent., developed myopia.

Average amount of myopia developed nearly 1 dioptic.

Thirty-four per cent. of the entire number were myopic at entrance, and 47 per cent. at graduation.

DR. R. MURDOCH, of Baltimore, exhibited to the Society and read a description of

A NEW COMBINATION OF INSTRUMENTS FOR USE IN THE EXTRACTION OF CATARACT,

among which was a new speculum, which absolutely prevents the patient from producing pressure upon the eye by any convulsive movement of lids while under ether during an operation. Such an accident may easily occur with the different forms of spring speculum in or

dinary use, either by the actual bending of the spring wire of which it is made, or by the slipping of the set-screw. The novelty of the instrument consists of two rigid arms, the lower attached firmly to a square, rigid, upright bar. On this upright bar the upper arm slides by means of a square sheath. When the arms are separated if any disturbance of the parallelism of the bar and its sheath occurs the friction is sufficient to prevent the approximation of the arms. So the more pressure applied at the extremities of the arms the firmer are they held apart. They are easily moved by pressure on the projection of the sliding arm at the bar end, as that immediately restores the parallelism of the square bar and its sheath.

Dr. Murdoch also exhibited an ophthalmostat, as figured, which, having been attached to the conjunctiva of the lower part of the globe, is easily affixed to the speculum, and so holds the eye immovable.

DR. H. S. SCHELL, of Philadelphia, read a paper on a case of

TUBERCLE OF THE IRIS.

When first seen the child had the iris bound down, and pupil would not dilate with atropine; apparently a case of plastic iritis. Family history of phthisis. Three weeks later returned with immovable pupil, with a small yellowish nodule, somewhat pinkish in color, upon the iris. Tension of eye increased. Painful. Had tubercular abscesses in other parts. Eye was enucleated, and a tuberculous mass found in ciliary region and in front of iris. Subsequent death of patient.

DR. O. F. WADSWORTH, of Boston, read a paper on a similar case. When first seen child had apparently kerato-iritis. A yellow reflex from pupil. Good family history. Child appeared to be well. Eventually had pain, with considerable injection of circum-corneal vessels. On iris a yellow growth with vessels running over it. The eye was enucleated, and the mass found to extend through the iris into the ciliary region. The vitreous was replaced by a serous fluid. The tumor was examined microscopically, and found to contain tubercles. The tubercle bacillus was also found. Child continued well five months; it was then attacked by severe headache which lasted six weeks, when the child died.

DR. S. F. MCFARLAND read a paper on a Personal Experience with Prismatic Glasses.

DR. O. F. WADSWORTH, of Boston, read a paper explaining the physical cause of the convexity or concavity of surfaces as seen through prisms.

DR. J. A. SPALDING, of Portland, Me., read a paper on Sympathetic Neuro-Retinitis.

DR. D. WEBSTER gave an Analysis of Thirty-Five Cases of Cataract Extraction.

DR. W. W. SEELY, of Cincinnati, read an article on Ocular Therapeutics.

DR. W. F. MITTENDORF read a paper on the

TREATMENT OF DETACHMENT OF THE RETINA FROM SEROUS EFFUSION* OR RETINAL HÆMORRHAGE.

He advocated a systematic and persistent attempt at the reduction of the serous effusion. To accomplish this he keeps his patient in a supine position, with both eyes closed, in a darkened room. Atropine should be used to destroy accommodative effort. No myotic. An elastic rubber bandage over the eye to induce absorption. He would hasten absorption also by the continued use of jaborandi and pilocarpine. It is his custom to give a hypodermic injection of from one sixth to one eighth grain of pilocarpine each morning; also to make a tea of jaborandi leaves with a strength of from forty grains to a drachm in twelve ounces of water. Of this he administers a teaspoonful dose every hour. This treatment, after the first disagreeable symptoms are over, continues as a state of merely comfortable diaphoresis, and is prolonged for twenty days or more. Specific treatment should be given if necessary.

CASES. Mr. S., forty years old. Myopic, which condition is hereditary. Left eye has complete cataract and is amaurotic, but has had no trouble from it for years. Two nights ago had a difficult motion of the bowels. Right eye suddenly became dim, and objects seemed red and green. Dimness of vision has increased since, and when seen tension was diminished and vitreous muddy, with total detachment of the retina. Amount of vision left very slight. Placed under treatment as above. At night patient distinguishes for the first time that the "doctor wears a beard."

Vision continued to improve, and at the end of three weeks has $\frac{1}{200}$ vision, with a fundus slightly blurred. One year later still had $\frac{1}{200}$ vision.

Mr. D., sixty years old, American. Left eye lost, but in good condition. Had a severe blow on right eye, and four weeks later, while at work in the field, became rapidly blind, with difficulty getting to the house. Was examined by a competent surgeon, and told that he had detachment of the retina. Six months later has almost entire detachment, but with perception of light in each direction. At the end of three weeks' treatment had $\frac{3}{200}$ vision, with a good field. Remained the same at the end of six months.

Mr. T., thirty-nine years old, German. Vision of right eye has been failing for some time, with floating opacities in vitreous. Tension normal. Diagnosis: Specific choroiditis. Put on specific treatment without improvement. Three weeks later became suddenly blind in both eyes. Tension rather less than normal. Was placed under above treatment with the biniodide mixture. Vision at end of three weeks in right eye $\frac{2}{200}$, left eye $\frac{1}{200}$.

DR. W. S. LITTLE, of Philadelphia, read a report of two cases of

ECTOPIA LENTIS,

in which vision was improved by cylindrical glasses, which have been worn for a year with comfort.

DR. GEORGE T. STEVENS, of New York, read a paper advocating

THE USE OF NITROUS OXIDE GAS FOR MINOR OPHTHALMIC OPERATIONS.

DR. BULLER, of Montreal, in the discussion which followed, said that it had been used in Moorfields', London, but had been given up on account of the venous congestion and a certain amount of rigidity of the muscles.

DR. HEYL, of Philadelphia, read a paper upon Glaucoma, and DR. G. HAY, of Boston, a paper illustrated by diagrams upon the Astigmatic Pencil of Rays.

DR. KIPP, of Newark, N. J., exhibited a Sarcomatous Tumor of the Choroid with interesting clinical features.

DR. S. THEOBALD, of Baltimore, read a paper upon

THE TRITURATION OF THE CORTEX.

This is the name recently given by Förster, of Breslau, to a method of hastening a slowly forming cataract. The method is this: a preliminary iridectomy is done upward in the same manner as for the Graefe extraction, and then while the anterior chamber is empty a gentle rubbing motion is made over the surface of the lens with some blunt instrument applied to the exterior surface of the cornea, thus bruising the capsule of the lens.

CASE I. Lens had remained in same condition for two years. Operation done as above, using for the trituration the angle of a strabismus hook. Increased opacity followed accompanied by iritis, which also complicated the convalescence of the subsequent extraction of the cataract.

CASE II. Opacity of lens had remained the same for many months. Operation done as above, and although there was still some clear lens before operation the red reflex had entirely disappeared in three weeks.

In the discussion which followed, DR. GRUENING said he had performed the operation twice without any iritis. He had used the end of the handle of the strabismus hook. Said great care must be taken to confine the trituration to the area of the pupil, new and old. Had removed cataract one week after the operation in the first case, and in the second the lens was quite opaque in four days.

DR. MITTENDORF said he had operated four times. Was successful in three cases, and lost one eye by iridocyclitis.

DR. WADSWORTH said he had performed the operation once without effect as to the ripening of the cataract. Had some slight adhesions of the iris to lens capsule.

DR. NOYES, of New York, had done trituration of lens capsule ten times, and once had had iritis, which repeated itself after the cataract operation; the nine other cases were successful. The time required in his cases to bring the lens into suitable condition for extraction was from three weeks to two months. It was noticed that the opacities did not invariably appear upon the surface which had been subjected to the treatment. Swelling of the lens does not occur as in traumatic cataract. Two of his cases had slight iritis. Used a silver curette.

DR. H. KNAPP, of New York, read a paper on Retinal Thrombosis with Blindness resulting from Facial Erysipelas.

DR. W. H. CARMALT, of New Haven, Conn., presented a paper upon

CHANGE OF REFRACTION THE RESULT OF A BLOW.

CASE. Student, thirty years old, struck right eye on a bolt in falling. Remained quiet the balance of the day, and consulted the reader a few days later, complaining that he could not see distant objects with right eye through the glass he was in the habit of wearing, but, on the contrary, without his glass saw better than he had ever seen before. Upon investigation it was proved that he had, previous to his injury, a myopia of $\frac{1}{2}$ in his right eye, and of $\frac{1}{4}$ in his left eye. Subsequent to the injury in the left eye the myopia remained as before, but in the right eye the myopia was reduced to $\frac{1}{8}$. Upon examination it appeared that the cornea remained unchanged. There was no alteration of the length of the eyeball. The lens images were not noticeably changed, and it was the opinion of the writer that the change in the refraction was due to a dislocation of the lenticular fibres.

DR. E. W. BARTLETT, of Milwaukee, read a paper upon a further modification of the cataract operation.

DR. E. GRUENING, of New York, read a paper upon

BLEPHAROPLASTY BY THE ENGLISH METHOD (ALLOPLASTY).

The writer applied the name of the English method to that class of plastic operations in which a piece of skin was transplanted from one portion of the body to another without a pedicle.

CASE. Patient had face burned. The cheek, nose, and forehead covered with firm cicatricial tissue. The skin of the upper lid entirely lost except the free ciliary edge, which was drawn back and attached to the supra-orbital margin. The piece of skin to be transplanted was selected on the arm, over the most prominent portion of the biceps muscle. The arm was thoroughly scrubbed with a carbolic wash for several days before the operation. The border of the lid was freed from its attachments. After the bleeding of the surface to be covered had entirely ceased it was measured, and a piece of skin of equal size marked off on the arm. This was cut on two sides, and the flap lifted up, the skin and subcutaneous tissue were dissected up carefully from the subcutaneous fat (an assistant grasping each lobule as it was raised with a pair of forceps), then separated, and transferred quickly to its place. Care should be taken that the surfaces applied together should be free from all spots of circumscribed bleeding, clots, or fat lobules. In order to accomplish this the sutures should be in position at the margins of the space to be covered before the skin is transplanted. The transplantation was dressed with boracic acid, and covered with gold-beater skin. At the end of twelve days, when dressing was removed, the transplanted skin looked clean, and there was sensibility at the edges although anæsthetic in the centre. Continued to do well.

DR. WADSWORTH said that he had reported such a case, and concerning the matter of sutures said if they were simply placed through the epithelium they were sufficient to keep the flap flat, and that all others should be omitted.

DR. J. GREEN, of St. Louis, advocated instead of sutures bridges of cotton fibres tied down with non-contraction collodion.

Other papers were read by DR. R. J. McKAY, of Wilmington, Del., upon the Loss of an Eye after Cataract Operation from Sewer-Gas Poisoning, by DR. L.

Howe, of Buffalo, upon the Difficulties of the Diagnosis of Glioma, and by Dr. HOLT, of Portland, upon Cases of Chemosia Retinæ.

The meeting of the Society was an instructive and enjoyable one, and adjournment was made for one year to meet at the same place.

Medical and Surgical Journal.

THURSDAY, AUGUST 2, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,

NO. 4 PARK STREET, BOSTON, MASS.

PROFESSOR SEMMOLA ON THE PATHOGENY OF BRIGHT'S DISEASE.

It has been a matter of dispute whether albuminuria has its origin in the blood, in the blood-vessels, or in the kidneys. The more modern view that its point of departure is the blood, and not the renal organs, derives striking support from the researches and experiments of Professor Semmola, of Naples. These experiments were made chiefly on dogs, and the results are published in the reports of the Academy of Medicine, June 5, 1883. Professor Semmola, following a line of experimentation instituted by him in 1850, injects subcutaneously in dogs and other animals abnormal quantities of albumen,—albumen of egg, milk, blood-serum, albumino-peptones,—and speedily renders them albuminuric. The animals are killed at different periods of the experimentation. When sacrificed twenty-four hours after the injection and absorption of an excess of albumen the kidneys presented no lesion, although the urine contained in the bladder was highly albuminous. This was regarded as a temporary albuminuria, and which, left to itself, would soon get well.

When the animal was killed at the expiration of four days the kidneys were found hyperæmic. Sometimes veritable hæmorrhagic infarctions were noted, even when the quantity of albumen injected was no larger than six to seven grammes per kilogramme of the animal's weight. On the tenth day there was a migration of leucocytes around the internal aspect of the capsule; the epithelia of the tubuli had commenced to degenerate fatty; the kidney was in the first stage of inflammation.

On the fifteenth day there was found to be marked augmentation of the inflammation, which kept on spreading till about the twenty-fifth day the connective tissue fibres were seen to be involved, and the lesions of the first period of interstitial nephritis presented themselves. The animals shortly succumbed to the serious disorders produced by this experimentation.

It was sought to demonstrate by these experiments

that the injection of albumen of egg produced more speedy and more grave lesions in the renal organs than when milk or blood serum was used. The nearer the albuminous substance used was like normal blood albumen the less irritating it proved to the uriniferous tubules. Professor Semmola has observed that patients in Bright's disease not only lose albumen in their urine, but also in all their secretions. If you cause them to perspire their sweat is albuminous; if you give them pilocarpine their saliva contains albumen in excess. Even the bile of these patients is albuminous. As a result of his experiments this writer concludes that Bright's disease is not essentially a renal affection, but a vice of nutrition, slow in its march, and produced often, if not chiefly, by suppression of the cutaneous respiratory functions, and characterized by an alteration of the albuminoid substances contained in the blood.

This vice of nutrition prevents the albumens of the blood from being assimilable, and they are eliminated as foreign substances by all the emunctories of the economy. The kidney is only one of these emunctories. This organ, whose excretory function is of such preponderating importance, having a large proportion of this altered protein element to remove, readily suffers inflammation, but such inflammation and its consecutive degenerations are secondary to the blood vitiation and the profound constitutional disorder.

These views are to some extent in harmony with those propounded by Mahomed in the *Lancet* in 1879. According to Mahomed the blood condition which produces the high arterial pressure of Bright's disease is the primary condition, and is not secondary to deficient renal excretion, as held by most authorities.

Semmola, however, merits a place apart from all others who have treated of the pathogeny of Bright's disease. He was the first to formulate the doctrine, since ably defended by Gubler and Jaccoud, and summed up in the following propositions of Gubler: "Albuminuria always indicates a relative or absolute excess of albumen in the blood." "Albuminuria recognizes for its cause a deviation from the normal type of nutritive movements; this deviation consists in a perturbation, temporary or permanent, of the phenomena of assimilation or disassimilation of albuminoid matters." This second proposition has for its basis a series of experiments which demonstrate that the filtrability of albumen varies according as its molecular state is modified by injections into the blood of water, common salt, or albumen; by the injection of certain substances which alter directly the blood corpuscles. It is this doctrine of molecular modification which is essentially Semmola's contribution to the pathogeny of albuminuria.

Two of Semmola's experiments, communicated to Jaccoud, and published in the second volume of his *Pathologie Interne*, are so striking, and throw so much light on the question, that they are worthy of reproduction here. A robust man is suffering from Bright's disease *a frigore*. Semmola takes from him three ounces of blood, isolates the serum, and injects twelve grammes in the jugular of a dog, from which he had

previously abstracted twelve ounces of blood. The urine of the dog becomes albuminous in two hours.

Consequently the albumen contained in the serum of the patient was in a molecular state which rendered it unfit for assimilation. Thirty-five days later the patient is completely recovered. Semmola again takes from him a little blood and injects twelve grammes of the serum in the jugular of a dog; no trace of albumen is found in the animal's urine. Therefore, concludes this sagacious experimenter, the albumen of the first serum was, by the fact of the disease, altered and unassimilable, the albumen of the second serum has become, by virtue of the restoration to health of the patient, completely assimilable. Dogs are painted over their whole body with an impermeable varnish, and become albuminuric. The serum of these animals is injected in the jugular of other dogs, is not assimilable, and renders these animals temporarily albuminuric. The serum of healthy dogs, injected subcutaneously, or in the jugular, produces no such result. Jaccoud, from whom we borrow these last facts, remarks that these experiments do honor to the fertility of conception and scientific tact of the professor of Naples, and he regards them as demonstrating the reality of the molecular alterations of the albumen of the blood, and the influence of these modifications on the filtrability of the albuminoid substances by the renal membranes and their passage in the urine. In other words, it is in the blood that resides the first cause of the disease.¹

THE FINE ART OF SUBSTITUTION.

He is very unsophisticated who supposes that the progress of industrial chemistry has been chiefly in the direction of furnishing the staples of life in greater abundance and purity. The chemist of a manufacturing institution is now called upon to know much besides the ostensible composition of the alleged product. Organic chemistry offers unbounded possibilities, and he who cannot bring forth any requisite color, odor, and flavor from the petroleum products has missed his vocation. From the pinnacle of modern science the versatile synthesist looks back with scorn at the feeble efforts of the early days of adulteration, when the crude milkman had no paraphernalia but his pump, and the sugar dealer's chief reliance was placed upon shifting sand. If we may believe what we are told even the old reliable adulterants are adulterated. It appears evident that the coming "boom" in applied chemistry is to be in the direction of synthetical rather than of analytical work.

In the *Revue des deux Mondes* (June 15th) is an article by M. Cochin presenting a glimpse of what is done in this line in the French capital. A number of dishes are mentioned, with an exposition of what they actually contain. For the sake of variety we will begin at the other end, and give the actual articles which the consumer introduces into his digestive apparatus, with a glossary for the benefit of the unin-

tiated; and in so doing we promise to chasten our imagination, and to base our bills of fare chiefly on the data given by M. Cochin.

A luncheon, from the two points of view, then, might be as follows:—

Chemist's Menu.	Caterer's Menu.
Potato starch. Alum, ammonia, starch, etc. White fish, antiseptic salts, aniline, etc. Copper. Earth, potatoes, lycoperdons, etc. Margarine, gypsum, silicate of potash, sulphate of baryta, coloring matters, vegetable and mineral. Peanut and cotton-seed oil. Chicory, corn, carrots, caramel, saw-dust, horse liver. Glycerine, terra alba. Cabbage leaves, willow leaves, "butts," snuff, etc.	Tapioca soup. Bread. Fresh salmon. Green peas. Truffles. Butter. "Huile d'olive." Coffee. Confectionery. Havana cigars.

If the diner has a mind to assist digestion (that is, chemical reaction) by a glass of wine, he stands just one chance in ten of getting the juice of the grape, while if he tries his fortune on cognac unfavorable possibilities are immensely increased. If he calls a physician to relieve his indigestion, the mineral water ordered is likely to have sprung from no greater depth than the druggist's laboratory.

M. Cochin explains some of the difficulties standing in the way of the inspectors of adulterations (for such officials exist even in Paris). The manufacturers are actually opposed to the municipal inspectors. They say that it is an encroachment on the "liberties of the people." The public demand water colored with aniline, logwood, etc., and it is better for them than alcohol, *ergo*, they should have it. After reading the manufacturers' protest and defense one is almost ready to grant that adulteration is a blessing, and that "not to do it is wrong." Again, these aggrieved persons point out that the inspectors by feeding popular prejudices hurt trade. What though the chemists find in 3361 samples of wine 202 harmful, 2802 passable, but adulterated, and only 357 irreproachable? These wines are no worse than other people's, and the Italian and Spanish authorities are no such fools as to damage their export trade by the publication of such trivialities.

Yet it should be said more seriously, in closing, that M. Cochin points out that the figures returned by the municipal laboratory are not so bad as they seem. The articles are examined because they are suspected. The ten specimens of milk, of which seven were adulterated, probably do not represent the average of the milk sold in Paris. Of one hundred persons tried for theft only ten may be acquitted, but that does not prove that ninety per cent of the community are thieves.

— A female passenger in an English steamer from Copenhagen to London, recently died, it is said, from sea-sickness. She was found dead in her cabin, and a medical examination, of which the particulars are not at hand, reached the foregoing conclusion, as she had suffered greatly from the malady during the voyage.

¹ *Semaine Medicale*, June 7, 1883. Jaccoud, *Path. Interne*, t. ii. p. 486.

MEDICAL NOTES.

— A Western paper says: "Sam Weldon was shot last night in the rotunda by Henry Parsons." About the worst place a man can be shot, next to his heart, is in the rotunda. It invariably proves fatal. — *Norristown Herald*.

— In a recent issue of the JOURNAL reference was made to Dr. Mundé's advocacy of the immediate and forcible removal of the placenta after abortions. On the other hand, Dr. Hiram Von Sweringen (*Obstetric Gazette*, June, 1883), with equal emphasis, cautions us to let the placenta alone after abortion. In addition to his own experience he cites that of many others, who all unite in the recommendation that it is best to leave the removal to nature. Rest and ergot are his therapeutic resources. If there is hæmorrhage, hot water injections; if much pain, opium; if it does not come away in two or three days, carbolized injections; but *never* force.

— Prof. O. P. Hubbard, M. D., LL. D., after forty-seven years of service, has resigned the Chair of Chemistry in Dartmouth Medical College. He has been made by the trustees Professor Emeritus. Prof. Edwin J. Bartlett, M. D., is to give the instruction in chemistry during the present course of lectures.

Two thousand dollars from the estate of Hon. E. W. Stoughton, for the benefit of the Museum of Pathological Anatomy, has lately been received by the trustees.

— The United States consul at Stockholm states in one of his reports that on the government railways of Sweden there is generally a physician for every fifty-two kilometres of the line of road, and forty-four physicians altogether are thus employed upon the government roads. The private railways have a medical service closely resembling this system. One of the duties of the medical men is to examine all applicants for employment, and those found laboring under any physical disability such as to disqualify them for duty are rejected. Particular attention is paid to color-blindness and other defects of sight and hearing among those engaged in the movement of trains. They are also required to give their professional services to all those who are entitled to the same.

Relief is granted to the following: (1.) All those injured by accidents upon the lines. (2.) In ordinary sickness to regular employees and their families. (3.) To other employees while in actual service. (4.) To laborers in the shops, who have paid the same contribution as is required of those in the operating department, and also to their families. (5.) To extra laborers who fall sick or are injured while on duty. All the above are also entitled to medicines at the expense of the company while under medical treatment. No exception is made against those who have contracted injury or disease by their own fault, as in case of drunkenness, brawls, or venereal infection.

— A memorial tablet to the late Professor Skoda, of Vienna, was unveiled with some ceremony on the 13th inst. The tablet is placed on the house in which Skoda lived and died, and the municipality have also,

in honor of the illustrious physician, changed the name of the street to "Skoda-gasse." There was a large attendance of the university students on the occasion, and, after a few words from Professor v. Arlt, Professor Schrötter, a pupil and friend of Skoda, made the speech of the day, in which he alluded to Skoda's labors not only in the cause of medical science and education but in sanitation.

— A man obtained a verdict of \$1000 damages against the city of Elkhart, Ind., for injuries sustained by being thrown from a wagon on an unfinished street. He asserted that kidney disease ensued. The city put a life insurance agent on his track, who induced him to make application for a policy. In this application he has made affidavit that he was not afflicted with kidney disease and never had been. The court has granted the city a new trial, and the authorities are congratulating themselves over the success of their stratagem.

— In the course of a dispute between the Chicago dealers in lard, it has been incidentally disclosed that most American lard is adulterated from ten to one hundred per cent. with oleomargarine, stearine, cottonseed oil, tallow, and terra alba.

— The following was found posted on the bulletin board of the Harvard Medical School after the late examinations:—

Dr. Edes wishes to call the attention of the graduating class to the following facts which may be important to them and their patients. The doses referred to are not all from books which failed to receive 50 p. c.

The following are too large doses:—

Half a grain of morphia, } to begin with.
Ten drops of Fowler's solution, }
10 c. c. of fl. ext. of conium.
Calomel, 7 grammes.
 $\frac{1}{2}$ or $\frac{1}{4}$ grain of sulphate of atropia.
1 gramme of sulphate of copper.

Half a gramme of aloes every night in habitual constipation.

The following would make inconveniently large pills:—

One gramme of pil. aloes et myrrh. (No such pill made is official.)

390 grammes of sulphate of quinine and 130 grammes of confection of roses made into 6 pills.

Seven grammes of calomel and six centigrammes of blue mass.

Pepsine and bismuth should not be given together.

Lactopeptine is less efficient than pepsine.

A teaspoonful of lime-water in a tumbler of milk does neither good nor harm.

Calomel should not be used as an habitual cathartic (as was recommended in a good many books).

Mercury alone cannot conveniently be made an ingredient of an extemporaneous pill.

Blue pill does not contain calomel.

"Hydrarg. corrosivi mitis" does not need¹ calomel (or anything else).

An apothecary cannot reasonably be expected to go out and kill a pig to make fresh pepsine for each prescription that comes in.

— Dr. A. Beclère has made a careful study of the conditions attending the contagion of measles, from which we select his more important conclusions: Rubeola is contagious from the commencement of the period of invasion to the end of the stage of eruption, a period extending through from eight to ten days. The contagious principle is contained in the secretion of the respiratory mucous membrane, and it

¹ Could not make out whether the word is NEED or REACH.

still remains to be proved that it has anything to do with the cutaneous desquamation. Although this contagion is diffusible, it is so only to a slight extent, and soon loses its active properties, and does not remain in the rooms occupied by the sick. The period of incubation lasts from thirteen to fifteen days; no immunity is conferred by the presence of any other eruptive disease. — *Gaz. Méd. de Paris*, February 17, 1883, and *Practitioner*, June, 1883.

NEW YORK.

— Although the temperature was considerably lower during the week ending July 14th than in the preceding week, there was no decrease in the death-rate, which was doubtless due to the fact that the effects of the extreme heat of the previous week were still felt in the community. The number of deaths was 1110, against 1061 during the week ending July 7th. Of the total number, 435 resulted from diarrhoeal diseases, and of these, 408 were of children under five years of age. The whole number of deaths of children under five years was 660; under two years, 607; and under one year, 517. Forty-three deaths were credited to the direct effects of the heat, and sixteen persons were found drowned. The deaths in tenement houses numbered 682. The number of cases of contagious disease reported for the week were as follows: Typhoid fever, 14; typhus fever, 1; scarlet fever, 42; cerebro-spinal meningitis, 1; measles, 71; and diphtheria 18.

— At the last meeting of the Board of Health Dr. E. H. Janes, assistant sanitary superintendent, reported that during the week ending July 13th the summer auxiliary corps of inspection had visited 3727 houses and 17,221 families, treated 621 cases of sickness, and distributed 1651 sanitary circulars, and 555 tickets for the excursions of the St. John's Guild floating hospital. Dr. W. A. Ewing, executive officer of the Night Medical Service, reported that twenty patients were treated in June, and that in each case the city had paid the legal fee.

— Up to the middle of July the floating hospital of St. John's Guild had made ten excursions. The usual trip of the boat is down the lower bay and around to the Guild's seaside nursery at Cedar Grove, Staten Island, which is now completely filled with children suffering from disease and prostration resulting from the hot weather. The cost of each excursion is \$250, and not infrequently the entire expenses of the trip are paid by a single individual or business firm.

— During the week ending July 14th there were 278,520 visitors to the city's free baths, of whom 77,816 were women and young girls.

— The report of the Brooklyn Health Department for the quarter ending June 30th shows that 933 cases of contagious disease were reported during that time. Of scarlet fever there were reported 1056 cases and 169 deaths; diphtheria, 310 cases and 105 deaths; typhoid fever, 27 cases and 15 deaths; whooping-cough, 81 cases and 29 deaths; and small-pox, 5 cases and 1 death. The number of children excluded

from school on account of contagious diseases was 3009, and the number of persons vaccinated by the vaccinating corps, 2390; 126 wells were condemned, and 6181 pounds of bad meat; 9 physicians were registered under the Night Medical Service, and the number of calls attended in this service was 17.

— The Board of Police have amended the rule in the police manual referring to sick-leave, with a view to prevent officers from feigning sickness. As it now stands it requires that all who report themselves as injured or sick shall remain in the police stations until examined by a police surgeon, and that if they are pronounced unfit for duty they must go to their homes, and remain there until reported by the surgeon as able to go on patrol.

— The average small boy can stand a good deal, but James Nevins, eight years old, who recently lived at Clifton, Staten Island, tempted Providence a little too much on one of the hottest days of the season. While helping a liquor dealer to move in the morning he fell down stairs with a child's crib in his arms, and was so jarred that he went home and lay down for a time. After he got up he refreshed himself with about a pint of apple-jack from a demijohn which he found unattended by the owner, and then went swimming. Remaining in the hot sun until he was completely prostrated, he was carried home, and again put to bed, but having slept through the usual family dinner hour he went out, and made a hearty meal of green apples in a neighboring orchard. Then, after playing awhile, apparently in good health, he drank a large quantity of ice-water before retiring, and the next morning was found dead. The verdict of the coroner's jury was that death resulted from apoplexy caused by the excessive use of liquor, aggravated by sunstroke.

— The steamer City of Washington, of the Alexandre line, which put into Havana with a number of yellow fever cases on board on July 19th, arrived at Lower Quarantine on the 25th, where she was detained until the following day, when she was permitted to come up the bay as far as Robbin's Reef and discharge her cargo by means of lighters. Her captain stated that while at Vera Cruz the ship lay at anchor three or four miles from the town, but that the air of the harbor was so deadly that even under these circumstances the fever gained a foothold on the vessel. She left Vera Cruz on the 13th of July, and soon afterward the disease broke out among the crew. Before Havana was reached twenty-seven persons had been taken down with it, including Dr. Caro, the ship's surgeon. The latter and three of the crew, among whom were the butcher and baker, died during the voyage to Havana, and were buried at sea. The only passenger attacked was General Ord, who subsequently died; and he with eight of the crew were sent ashore at Havana and placed in the hospital there. The other patients were in a fair way of recovery by the time that port was reached, and there were no deaths afterwards. A new surgeon, as well as a number of new hands, were procured at Havana. When the City of Washington reached Lower Quarantine

the Health Officer found no sickness whatever on board and she was detained there merely on account of the rule which requires vessels from Havana to be quarantined until they have been five days out from that port. The mails were thoroughly fumigated before being sent up to the post office. The strictest vigilance is now being observed by the authorities in regard to all vessels from suspected ports, especially those of the Mediterranean, and it is believed that on account of the precautions taken there is no danger of cholera being introduced through the port of New York.

— Orders have recently been issued by the Health Officer to disinfect at quarantine the rags which are usually rolled around marble imported from Italy before permitting the vessels containing such cargoes to pass up to the city.

— On the 24th of July officers and inspectors of the State Board of Health served orders signed by the Governor on thirty-two firms and corporations along Newtown Creek from Hunter's Point, Long Island City, to Newtown, directing them to abate the nuisance of foul odors from their various manufacturing establishments, which have so long imperiled the health of the residents of the vicinity. The stench from these factories has been a subject of complaint from the citizens of Queen's County, as well as of New York, whither it is always wafted when the wind is easterly, for years, and Newtown Creek, by reason of the filth which has been allowed to drain into it, has been converted into a disease-breeding stream. Several other attempts have been made to abate the nuisances, but up to the present time have always proved ineffectual, principally because they have been made in such a public manner that the proprietors of the establishments have been forewarned, and thus have temporarily corrected many of the abuses. The proceedings this year were taken in a very quiet manner, and until the orders of the Governor were served upon them it is probable that not one of the firms charged with sustaining a public nuisance was aware that any investigation of their business was being made. On the 9th of June the attorney for the Long Island Railroad Company presented a petition from a few residents of Queen's County reciting the fact that Newtown Creek was lined with factories from which insufferably offensive stenches, which were dangerous to life, constantly arose, and asking for an abatement of these nuisances. The Governor, who was requested to keep the matter secret, at once referred it to the State Board of Health, which instead of beginning a public investigation, as in 1881, and thus putting the implicated parties on their guard, quietly sent a number of experts to the locality named to examine into the complaints. The result was that the inspectors, after nearly a month's labor, reported thirty-two establishments as public nuisances. The Board of Health made an elaborate report to the Governor recommending the abatement of these nuisances, and the Governor promptly signed the orders directing the offending companies either to remove their factories altogether or immediately take such measures as would render them inoffensive to the

community at large. Officers acting under the direction of the State Board of Health have been detailed to watch the nuisances, and see that the orders are executed in accordance with the provisions of the law; the penalty for non-compliance with which is a fine not to exceed \$1000, imprisonment for not more than one year, or both fine and imprisonment.

— Dr. Milligan Patchin, one of the summer corps of Board of Health physicians, having committed suicide by shooting himself in the head, Dr. Ellsworth E. Hunt has been appointed in his place.

Miscellany.

ON SOME RECENT ADVANCES IN THE SURGERY OF THE URINARY ORGANS.

BEING THE ADDRESS ON SURGERY DELIVERED BEFORE THE FIFTY-FIRST ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION, AT LIVERPOOL, ON AUGUST 1, 1883.

BY REGINALD HARRISON, F. R. C. S.,
Surgeon to the Liverpool Royal Infirmary.

MR. HARRISON, by way of introduction, remarked that one advantage connected with the itinerant character of the meetings was that the different places suggest references to local celebrities of the past whose works cannot be thought over without advantage. He then referred to former surgeons of Liverpool.

In considering the position of surgery as detailed in Dr. Stokes's admirable address of last year, the thought naturally occurs that its diffusion is as remarkable as its progress. Compare, for example, the condition of surgery prior to the existence of our Association with its position as set forth in the columns of journals of the present day. In the former period departures from the ordinary routine of surgical procedure were confined to a few hands, and the benefits resulting from improved methods of treatment were shared in by a very limited number. Now no sooner is a method of treatment or an operation proved to be efficient than it is taken up and practiced wherever scientific surgery can reach; the peer is no better off than the peasant, and the cottage hospital rivals in its successes its more palatial representative.

The remainder of the address was devoted to more recent work in connection with the surgery of the urinary organs.

Commencing with the kidneys, Mr. Harrison considered it premature to formulate anything like precise rules, but from recent publications we may draw at least three conclusions of value:—

- (1.) That nephrectomy has been the means of saving many lives under circumstances where no other method of treatment was likely to be of service;
- (2.) That this operation has been practiced in cases where the probability of a successful termination appeared to be very remote; and
- (3.) That a method of effecting the removal of the organ different from that which was selected or a procedure less heroic might, in some instances, have tended to increase the chances of success.

In these directions then—in selecting cases for operation, in rejecting others as unsuitable, and in deter-

mining relatively to the case in question the best method of procedure—I take it that good work has yet to be done.

Till a few years since the removal of stone from the bladder by crushing had been conducted on the lines laid down by Civiale some half century ago. Though this method of proceeding has included amongst its advocates, past and present, surgeons of eminence, it cannot be said that as then practiced it was either gaining ground or confidence.

Whilst the surgical mind was thus to some extent in doubt as to the limits to which the crushing operation of stone might safely be pushed, two important communications followed rapidly upon each other. That both of them should have emanated from America merely indicates that the desire to advance the art of surgery is not limited to the old country, but is a natural outcome of advancing civilization and humanity.

The first of these papers was by Dr. Otis, of New York, who demonstrated beyond all reasonable doubt, and in a manner which had not previously been attempted, that the male urethra was capable of safely receiving far larger instruments than were generally employed. Following upon this, and probably influencing the views of the author, came Dr. Bigelow's paper on the removal of stone from the bladder by crushing and withdrawing it at a single operation; the latter communication clearly showing that the bladder was tolerant of much more prolonged manipulation than had previously been believed.

It appears to me that the originality of Bigelow in no way detracted from the importance of the work that had previously been done in this country and elsewhere, or compromised the acumen of those who were most interested in the progress of this department of surgery.

That Bigelow's method of procedure is a great step in advance—that it has extended the limits of lithotripsy and curtailed those of lithotomy—there cannot be the least doubt.

May not a more perfect knowledge of the physical and physiological laws which regulate the production of concretions in the human body result not only in enabling us more surely to prevent them, but to destroy them?

I cannot help thinking that if it could be shown to be even probable that the dogs, cats, rabbits, or frogs of the aforesaid districts were inconvenienced in a like manner with their owners, the matter would long ago have been forced upon our legislature with all the exaggeration that usually characterizes agitations of this kind.

It appears to me that enlargement of the prostate is especially interesting to us in relation to its earliest and to its most advanced forms, and it is to these points that I shall more directly refer.

If we take the obstructive disorders of the urinary apparatus, and inquire what feature of them is most detrimental to the associated parts, the answer undoubtedly will be, The misdirection of the muscular force that is thereby entailed. How can we explain the structural alterations which take place behind the obstructed point, and which manifest themselves in different ways, except as the results of urinary retention and retrograding pressure. How frequently do we find, in cases of stricture or enlarged prostate, that the whole of the apparatus behind the primary con-

striction consists of little else than dilated saccules and tubes. Is not this back-pressure going on, though it may be imperceptible, from the moment that impediment arises to the escape of urine from the bladder? The more we study animal mechanics, either in their physiological or pathological application, the more can we appreciate the truism that force is never lost; if it is not permitted to act for good, it must be productive of evil; if it is not exerted towards the legitimate fulfillment of a normal act, it must inevitably exercise a corresponding pressure in an abnormal direction. Whenever I see in the post-mortem room an ordinary specimen of dilated kidney, tortuous ureter, or sacculated bladder associated with an enlarged prostate, or a stricture, the expression "misdirected force" almost involuntarily escapes from me.

Such considerations as these have long led me to believe that our treatment of prostatic stricture commences, as a rule, far too late; we delay until the bladder shows, by the formation of a pouch or a saccule, behind the prostate, the first bad influence of back-pressure before we seek to rectify it.

I have endeavored to prove how much good may be done by the adoption of judicious mechanical treatment on the appearance of indications that the prostate is commencing to obstruct micturition, and I have founded my suggestion upon a condition which may be seen illustrated in any museum, namely, one in which, though the gland has become large, obstruction has not been known to occur. An extended adoption of this practice has convinced me that the pressing symptoms connected with an enlarging prostate may be kept in abeyance by the timely employment of those principles of treatment which are generally recognized as being applicable to any tubes within the body which are threatened with occlusion and are within our reach.

In the more advanced forms of prostatic enlargement, where the bladder has been converted into a receptacle little better than a chronic abscess in which urine stagnates, surgery has done much to afford relief.

When the comfort that catheterism is capable of affording has ceased to be effectual, other plans of establishing a drain for the urine are at our disposal. It is not necessary that I should discuss the various means of effecting this; let me, however, say a few words in reference to two which have more recently come under notice; these are, first, incision into the bladder from the perineum, and secondly, paracentesis through the enlarged gland.

For the purpose of securing a more or less permanent channel for the escape of urine from the bladder, other than that by the urethra, I must admit that following the practice of Syme, and to some extent of Edward Cock, I have a decided preference for an incision through the perineum, on the twofold ground of safety and comfort. We have had numerous examples of the great advantage that cystotomy is capable of affording for bladder affections, dependent on a large prostate—none perhaps more striking than the case narrated by Mr. Lund, on the memorable occasion of the meeting in London of the International Medical Congress. The paper closes with this observation: "I have thus placed on record this case, unique in its character, and interesting and encouraging in its results, with the hope that should a similar case occur to any surgeon now present, he will not hesitate to give

his patient the chance of benefit from a course of procedure so simple in its nature, and so likely to be followed by temporary, if not permanent, benefit."¹

I may be permitted here to submit to your notice a method of puncturing the bladder through the enlarged prostate which has afforded very gratifying results. It consists in passing the trocar through the gland, and retaining it in the perinæum, so as to afford a permanent as well as a convenient drain for the urine. I should have had more diffidence in commending this operation to your notice had it not received the approval of our distinguished associate, Professor Gross, whose contributions to the Surgery of the Urinary Organs are held in deservedly high repute on both sides of the Atlantic.

Though the primary object of cystotomy, as usually practiced, is merely to place the bladder at rest, by providing a continuous drain for the urine as well as the products of cystitis, it occurred to me, as it had already done to others, that it would be possible to extend this proceeding, with the view of removing those barriers to micturition which the hypertrophied gland so frequently presents.

It was to meet conditions such as these that Mercier introduced and practiced division of the prostatic bar by means of a cutting instrument introduced along the urethra. This plan, though admirable in its conception, was open to the objection that in its execution it was necessarily uncertain, there being no means of ascertaining with certainty that the section was confined to the obstruction to be removed. On carefully considering the position of matters, as well as the proposals that had been made, it appeared to me more reasonable to attempt to divide the prostatic obstruction at the neck of the bladder from an opening made into the membranous urethra, than by means of instruments which had to traverse the whole length of the canal. I have recently brought under notice a case² in which I thought it desirable to explore the prostatic urethra from an opening made in the perinæum, through which I was enabled to divide with precision a prostatic barrier. The division of this portion of the gland was followed by complete restoration of the power of micturition, and has so far proved of permanent advantage.

The proceeding which I have thus put into practice seems first to have suggested itself to Mr. Guthrie, but I cannot find that he ever employed it; that it is not identical with the somewhat extensive incision of the prostate as for lateral lithotomy which was practiced by Sir William Blizard is at once obvious. Its aim is to divide the obstruction — and the obstruction alone — by an opening so planned as not to expose the patient to undue risk; whilst, at the same time, it is capable of affording the greatest amount of room for manipulation by an extension of the incision, should this prove to be necessary.

I need hardly observe that a proceeding of this kind should be undertaken before the bladder has passed into a condition of confirmed and irremediable atrophy; otherwise, though we may succeed in removing an obstacle to the introduction of the catheter, our prospect of restoring the power of micturition will be as hopeless as it has proved to be under somewhat similar circumstances where the operation of lithotomy has been undertaken.

It is impossible to avoid the conclusion, from their examination after death, that many atonied bladders might have been prevented becoming so by the timely removal of the obstruction by which a condition of permanent paralysis was induced and maintained.

The operative treatment of the enlarged prostate, when it obstructs micturition to a degree that cannot be met by judicious catheterism, is yet, I believe, open to considerable improvement.

Though the literature relating to either complete or partial excision of the prostate is very limited, there is much in it of promise. In one case, where I extirpated the whole gland for malignant disease, the benefit that followed far exceeded my expectations. It was that of a middle-aged man who, by reason of a carcinomatous prostate, was threatened with a speedy and painful death. I cut down upon the gland in the median line, and succeeded in enucleating it tolerably cleanly with my finger. I saw this patient eight months afterwards in very fair health, and quite able to go about his business. So far he has enjoyed an immunity from the symptoms which induced me to perform this operation, and though his disease is a malignant one, we have every reason to be content with the results obtained.

Then we have numerous examples where considerable masses of the prostate have been removed with very great advantage in the course of operations on the bladder. Amongst these I would specially mention an important case by Mr. Bickersteth; and, more recently, another by Dr. John Ashhurst, of Philadelphia, in which the whole of an enlarged third lobe was successfully removed.

Cases such as these seem to favor the hope that operative surgery will be found capable of affording more relief to exceptional instances of this kind, and of extending to the large prostate the treatment which in some degree is applicable to other deep-seated growths.

Mr. Harrison then expresses his dissent from the views of Ovis in regard to the necessity of internal urethrotomy, and, with allusions to various other matters connected with urethral and general surgery, concludes by saying that there need be no hesitation in asserting that whether we are regarded as preventers of disease, or as practitioners of surgery or of medicine, every one of us in his daily practice carries with him a proof that year by year something additional is contributed by our profession to the comfort and the life of man.

THE DIAGNOSIS OF TÆNIÆ INTESTINALES.

A WRITER in the *Dublin Journal of Medical Science* (May, 1883) emphasizes the importance of making a diagnosis between the *tænia solium* and the *tænia mediocanellata*, because of the greater difficulty in treating the latter and because of the possibility, as he considers, that the drug most valuable against one variety of the parasite may not be the most so against the other. The differential diagnosis can be easily made by a naked eye examination of the *proglottides* or mature segments, which are found in the stools; or, if the segments at the time of examination are too opaque, place one of them on a glass slide, let it dry, and then all the necessary parts for examination become very distinct.

The mature segments of *tænia solium* measure half

¹ Trans. International Medical Congress, vol. ii.

² British Medical Journal, June 9, 1883.

an inch in length by a quarter of an inch in breadth; have the genital pore on one or other lateral border, and midway between the anterior and posterior extremities; the elongated uterus has only from twelve to fifteen lateral branches. The segments of *tænia mediocanellata*, on the other hand, are much larger, the length being one inch, and the breadth nearly half an inch; the genital pore, as in the former case, will be found on one or other lateral border, but nearer the posterior than the anterior extremity; the uterus, which is elongated, possesses from thirty to thirty-five lateral branches on each side. *Bothriocephalus latus* occurs more rarely, but its segments are easily known, by being broader than long, having the uterus and its branches arranged in the form of a central rosette, and the genital pore on the surface.

In a case reported by this author incomplete removal of the parasite was effected some seven times, the usual agent being one-drachm doses of *ex. filicis fl.*, accompanied before and after by cathartic pills. The successful agent was a three-drachm dose, repeated in three hours. He considers that the ordinary dose recommended in the British Pharmacopœia (twenty to thirty minims) is quite inadequate.

OPERATIVE TREATMENT OF CANCER OF THE TONGUE.

THE steps of Billroth's method are reported in the *London Medical Record* as follows: Both lingual arteries are first ligatured; the mouth is then kept open by a speculum, and all diseased teeth opposite the ulceration are extracted. The gum is next separated from the inside of the lower jaw with the raspator. Excision of the floor of the mouth is then effected by means of scissors and forceps. The bleeding points are ligatured, and the tongue, being drawn forward, is finally extirpated. After the separation of the organ, permanganate of potash, either in powder or in watery solution, is applied to the wounded surface, and a drainage-tube, of the thickness of a finger, is inserted through the floor of the mouth. Through this the various discharges escape, and diphtheria of the mouth, cervical phlegmon, and broncho-pneumonia, do not occur in such cases when properly drained. The patients are fed by means of a stomach-tube, until the drainage opening has quite closed.

The proceeding is not so severe as the methods of Langenbeck and of Regnoli and Czerny; and the immediate results of the operation are more favorable than by any other plan, namely: 84.2 per cent. of recoveries. The deaths were caused by septicæmia (acute or chronic) or by pyæmia. In seventy-one cases ten radical cures have been obtained (fourteen per cent.) by Professor Billroth; while in 373 instances of mammary excision only fifteen radical cures have resulted.

SALICINE IN RHEUMATISM.

A WRITER in the *Lancet* (May 5, 1883) speaks favorably of salicine, the natural product of the willow root, as often giving better results than salicylic acid, the artificial phenol derivative. He says that while the latter will sometimes sicken even in moderate doses, almost any quantity of the former can be given, and records two cases of acute rheumatism rapidly cured by

its use. He advises it in large and frequently-repeated doses. One of his cases took eighty grains in one dose, daily, for three days without any bad effect. Salicine in very large doses is most easily taken by stirring it into a hock glass of milk, which the patient rapidly swallows before it has time to settle down from its suspension. It may also be taken in wafer paper, or even in water, but in this case the bitter flavor is felt. It should always be taken on an empty stomach; after food it often occasions nausea and tinnitus. He believes that its value in acute rheumatism cannot be over estimated, and that should the physician get hold of the case early he will likely be able to conquer it before there is time for cardiac complication, so apt to leave enduring mischief behind it. Finally, when the rheumatic sufferer convalesces, the salicine should not be dropped too suddenly. For a week it should be given in full doses morning and evening, and for a fortnight once daily; otherwise a relapse may supervene. A notable feature in the salicine treatment is its tonic effect in promoting a steady and rapid recovery of strength and vigor during convalescence.

It is very cheap, selling in England, at retail, for less than twenty-five cents per ounce.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM JULY 20, 1883, TO JULY 27, 1883.

SUTHERLAND, CHARLES, colonel and surgeon, medical director Military Division of the Pacific and Department of California. The leave of absence granted by S. O. 64, headquarters Military Division of the Pacific, June 30, 1883, is extended two months. S. O. 168, A. G. O., July 23, 1883.

BAILY, JOSEPH C., major and surgeon. Assigned to duty as post surgeon at Fort Concho, Texas. S. O. 87, headquarters Department of Texas, July 19, 1883.

APPEL, A. H., first lieutenant and assistant surgeon. Granted leave of absence for two months, with permission to apply for an extension of one month. S. O. 30, headquarters Military Division of the Atlantic, July 20, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING JULY 28, 1883.

GATEWOOD, J. D., passed assistant surgeon, detached from the New Hampshire, and ordered to hold himself in readiness for sea-service.

LEACH, PHILIP, assistant surgeon, detached from the receiving ship Franklin and ordered to the New Hampshire.

HORACE B. SCOTT, assistant surgeon, ordered to the receiving ship Franklin, Norfolk, Va.

McMURTRIE, D., surgeon, detached from the receiving ship Franklin and granted sick leave.

WHITING, ROBERT, passed assistant surgeon, granted one month's leave.

APPOINTMENT. — Dr. Edgar A. Dean, of Brockton, has been appointed a member of the Massachusetts Board of Health, Lunacy, and Charity, to succeed Mr. C. F. Donnelly, whose term of service had expired.

DR. L. S. McMURTRY has retired from his editorial connection with the *Louisville Medical News*, and Dr. H. A. Cottell resumes his former connection with that journal.

BOOKS AND PAMPHLETS RECEIVED. — A History of Tuberculosis from the time of Sylvius to the present Day, being in part a Translation, with Notes and Additions, from the German of Dr. Arnold Spina; containing also an account of the Researches and Discoveries of Dr. Robert Koch and other Recent Investigators. By Eric E. Sattler, M. D. Cincinnati: Robert Clarke & Co. 1883.

Original Articles.

A CONTRIBUTION TO THE STUDY OF THE TUBERCLE-BACILLUS.¹

BY HAROLD C. KÄNST, M. D., JAMAICA PLAIN.

At a medical meeting in Vienna, on May 13th, Spina² read a paper on the subject of Koch's bacillus. It was especially devoted to the discussion of its behavior towards staining fluids, and he still denies any specific property to it. He gives no further inoculation or cultivation experiments, and bases his rejection of Koch's theory especially upon the fact that the bacilli are found to act otherwise toward staining fluids than it was at first announced they did.

In proof of the presence of other organisms having the same staining reaction he gives the result of Dr. Matray's work, which is as follows:—

(1.) Micro-organisms of many kinds, especially staff-shaped bacteria, cocci singly and in colonies, leptothrix and torula forms, were stained blue on a brown ground: (a) in bronchiectic sputum; (b) in sputum of bronchial asthma; (c) in sputum of diffuse bronchitis (every time in ninety-four preparations); (d) in the "furred tongue" of non-phthisical patients (eleven cases with twenty-eight preparations); (e) in the lochia of non-phthisical lying-in women (twelve cases with forty-three preparations); (f) in the sputum of fourteen cases of pneumonia (forty-six preparations); (g) in the stools of a typhus-fever patient; (h) in the expressed fluid of a case dead of malignant oedema.

(2.) Bacilli in form, size, grouping, and reaction like the tubercle-bacilli were seen: (a) in the sputum of a case of bronchiectasis (in fifty-four preparations); (b) in the furred-tongue secretion of sick and well persons (eleven cases, twenty-eight preparations); (c) in the stools of a typhus-fever patient (every time in sixteen preparations); (d) in the sputum of a case of bronchial asthma (every time in thirty-four preparations); (e) in the sputum of a case of diffuse bronchitis (six preparations); (f) in the lochia of a healthy lying-in woman (two preparations); (g) in a case of croupous pneumonia (four preparations).

He quotes Kaberhel and Matray (assistants assigned to him by Stricker) as concluding that, "on the one hand, micro-organisms which do not differ from the tubercle-bacillus react to staining fluids as do these bacilli; and, on the other hand, that Koch's bacilli react to staining fluids exactly as do other micro-organisms."

He also quotes, as a point against the specific nature of the tubercle-bacillus, the recent observation of a bacillus similar to these in several cases of lupus.

Stricker himself addressed this meeting in support of Spina and his methods.

Klebs,³ as the result of his more recent work, gives the following summary:—

(1.) The tuberculous process is caused by organisms, as was first shown by me, and rendered certain by R. Koch.

(2.) I have not come to the same results as Koch in regard to the morphological relations of the tuberculous organism. On the one hand I must hold fast to the fact that finely granular micrococci are present in

the albumen cultures, as well as in the youngest form of inoculated tubercle. On the other hand I am in no way meaning to assert that Koch's bacilli are essential impurities. They appear to represent an essential stage of development of the tubercle organism for the further development of tuberculosis, if they are not always present.

(3.) In regard to the history of the development of tuberculosis I think that I have presented the proof that:—

(a.) The development of the tuberculous process begins very soon after the inoculation, and not after from ten to fourteen days, as Cohnheim and others believe. The difference depends, not upon an error of these last investigators, but upon the nature of the changes which are to be regarded as the first stage of the tuberculous process. Completely formed tubercles, which can be distinguished with the unaided eye, appear in fact only after the longer period. But before the appearance of these there are already extensive cellular deposits present in places which are at a great distance from the place of inoculation (mesentery). These represent perivascular infiltrations which are either developed further to the known form of tubercles or can retrograde in the different stages of their development (cheesy nodules, either with or without contracting cicatrization, adhesive and deforming forms of peritonitis).

(b.) The same primary method of distribution is also found in human tuberculosis, in which also the traces of these retrogressive formations in the mesentery and omentum are found in cases of pulmonary tuberculosis. In other cases, on the contrary, a further development of this form of tuberculous invasion comes on, which leads to the formation of cheesy foci in the organs, which are only related by means of the blood-vessels with the point of entrance of the tubercular virus into the organism (cheesy foci of the bones, the central nerve apparatus, etc.).

The work which I have done upon this subject has been for the purpose of identifying the bacillus and determining the frequency of its occurrence in tuberculous lesions. The organs examined have been lungs, liver, spleen, kidney, peritoneum, bronchial, mesenteric, and inguinal glands, pia mater, and the eye. In all of these bacilli have been found in varying numbers. They are less numerous in old, or slow, processes; very abundant in rapid ones, and especially so in the cavities filled with cheesy material. They are found in the swollen epithelioid cells of tubercle, or lying between them—singly, or in groups of from two to a dozen or more. They very frequently seem to be divided into a series of dots, from four to six in number, which occupy the body of the staff, and are taken to be spores. The result of my observation is confirmatory proof of the existence of the bacilli, and of Cheyne's proposition that their presence is diagnostic of tubercle. The difficulty with which they have been demonstrated in some cases and the care required to obtain the desired result seem to explain some of the failures in this direction. Nothing less than a one twelfth Zeiss objective, together with an Abbé's illuminator, is sufficient for the perfect examination of a section. All my observations have been made with this apparatus and a No. 3 eye-piece. All the sections have been made with a Jung microtome. Upon several occasions the bacilli have been observed in the blood-vessels, which would seem to show one method

¹ Concluded from page 104.² Spina, Wien. Med. Presse, May 13, 20, 1883.³ Klebs, Virchow's Arch. f. Exper. Path. und Pharm., Band xvii., s. 51.

of auto-infection; the lymph channels undoubtedly furnish another. I have seen a bacillus lying half in, half out of, a swollen cell, its presence seeming to have acted as an irritant upon this special cell element. I have never seen anything but the bacillus staining red on a blue ground, although there have been plenty of other organisms which were stained blue.

The method of staining employed has been practically that of Ehrlich, which has seemed to give the most satisfactory results. It is as follows:—

For sputum: The cover-glasses are spread with a thin layer, taken from the more solid portion of the specimen, using fired platinum needles for its distribution. They are then dried carefully over the flame of an alcohol lamp, and after drying are passed two or three times through the flame itself. They are then placed in a solution of Fuchsine B. and aniline oil,—one gramme of the first to fifty grammes of the second. The latter is made by shaking a few drops of aniline oil with distilled water, and filtering. The specimens are allowed to stand in this solution for twenty-four hours. They are then washed and placed in a solution of one part of nitric acid (C. P.) and two parts of distilled water, and allowed to remain until they are completely decolorized, or until at the most a pinkish hue is all that is left visible to the eye. All the acid is then removed by repeated washing in distilled water, and the specimens are placed in a saturated watery solution of methylene-blue, and allowed to remain for five to eight minutes. The superfluous staining fluid is then removed by repeated washing, the specimens are carefully dried as before, and are finally mounted in Canada balsam and examined.

For the tissues a similar method was pursued, except with the differences made necessary by their nature. Before placing in the Fuchsine solution the alcohol should be removed by thorough washing, and the reagents should be allowed to act for a longer time, more especially when the sections are thick or the specimens are old. After staining in methylene blue they should be washed, dehydrated in alcohol, cleared up in oil of cloves, and mounted in Canada balsam.

The following is a complete record of the examinations I have made of different organs for the detection of the bacilli:—

No. I. A guinea-pig inoculated in the groin with a few drops of tuberculous sputum in December, 1882, died in the middle of January, 1883.

Sections were prepared from the liver, spleen, and peritoneum; the lungs were healthy.

No bacilli were found in the sections of the liver.

The spleen showed bacilli singly in the tissues and in the swollen epithelial cells.

The peritoneum contained bacilli in the miliary nodules, about the edges, and in the centre of the tuberculous mass.

No. II. A guinea-pig inoculated in the same manner as the preceding, died January 13, 1883.

No changes in any organ but in the liver.

Slides from this showed the bacilli in numerous places in and near the tuberculous portion, which was in the form of infiltration rather than of nodules. The general position of the bacilli was in the lymphoid cells, and rather in the region of the portal vein.

No. III. A guinea-pig inoculated as the preceding, in December, 1882, died in March, 1883.

The lungs presented no abnormal appearances.

The spleen showed plenty of evidence of degenera-

tion, and bacilli were found in numbers in the cells and lying free in the tissues.

The liver and an enlarged inguinal gland were examined, with negative results.

No. IV. A guinea-pig inoculated on March 13th with a few drops of tuberculous sputum (from Case IV.); the syringe was inserted in the left inguinal region just under the skin. Died in ten days.

All the organs gave negative results, except in the spleen, where, with no changes visible to the naked eye, a number of bacilli were found in and near the finer blood-vessels.

The cellular tissue at the point of inoculation was found to be stuffed with bacilli, lying in and between the much swollen cells, and in immense numbers.

No. V. A guinea-pig inoculated in the same manner as the first three in December, 1882, died, after progressive emaciation, on April 2, 1883.

All the organs showed tubercular infiltration, and sections under the microscope showed bacilli in the lungs, liver, spleen, kidney, inguinal glands, and skin under the point of inoculation.

No. VI. A guinea-pig inoculated in the eye in December, 1882, died April 15, 1883.

The lungs, liver, and glands showed signs of disease.

The bacilli were found in plenty in the giant cells and the alveolar walls of the infected portion of the lungs, and in smaller numbers in the cells, and lying free at the edges of the tuberculous deposit in the liver. They were also found in the gland examined.

No. VII. A child of three and one half years died of acute miliary tuberculosis.

Sections from the lung, liver, and mesenteric gland showed bacilli very distinctly. Slides from the liver and peritoneum were unsuccessfully mounted and gave negative results.

No. VIII. A cheesy bronchial gland, removed three months before examination, and preserved in absolute alcohol.

Bacilli were found in plenty in the cheesy portions near their edges; fewer in the degenerated parts, and scattered through the comparatively healthy tissue beyond.

No. IX. A case of acute miliary tuberculosis in a child.

Sections from a peritoneal gland and the liver gave negative results; there was no tuberculous infiltration on the slides prepared.

The sections from the kidney contained very little tuberculous infiltration. Bacilli were noticed in small numbers in the region of the straight tubules, and a few in the interior of swollen Malpighian bodies.

The omentum contained occasional masses of bacilli, with numbers of isolated staffs in the infiltrated tissue.

No. X. A specimen marked "Gland from Autopsy."

But two slides were prepared from it, and gave no evidence of the presence of bacilli.

The specimen was very old, and had no attainable history; it may therefore be fairly rejected as evidence.

No. XI. Tuberculosis of lung.

A specimen of very old fibroid phthisis. The tissue under examination was almost all cicatricial, and nothing was seen that could be distinctly made out as the bacillus.

No. XII. Tuberculosis of peritoneum.

The nodules were extremely fine and widely separated, and a section of one was not obtained. Bacilli were seen, however, in small numbers, lying singly in the tissues where the presence of swollen cells indicated the neighborhood of the tuberculous process.

No. XIII. This was a specimen sent in as a "cheesy mesenteric gland," from a case in which death was caused by the perforation of an ulcer of the intestine into the peritoneal cavity and the subsequent peritonitis.

There was no tuberculous disease of the gland at all, and bacilli were not found.

No. XIV. Contents of a cheesy cavity from the lung of a rapidly fatal case of tuberculosis.

Bacilli were found in immense numbers; in some cases the cells seemed to be stuffed with them, and most of them showed a well-marked division into spores.

No. XV. Scrapings from the wall of a lung cavity in an ordinary case of phthisis.

Bacilli in immense numbers. In some places the whole field filled with them.

No. XVI. Contents of a lung cavity in a case of slow tuberculosis.

Bacilli in immense numbers, in masses and singly, and presenting well-marked divisions into spores.

No. XVII. Cheesy cervical gland.

Largely made up of fibrous material, with a few small cheesy foci. Bacilli were found in the edges of these portions in clumps and singly, and in the few giant cells that were seen.

No. XVIII. Case of tubercular meningitis; dead after a month's illness.

A much enlarged bronchial gland was found, and the pia mater was full of minute granulations.

Bacilli were found scattered about near the edges of the tubercular portion of the gland, with many spores.

Sections of the pia mater showed very fine bacilli, with many spores, their situation being, in general, in the neighborhood of the finer blood-vessels and the lymph spaces. The origin of infection in this case was very evidently the enlarged gland.

No. XIX. Tuberculous lung.

This specimen was a mass of tubercle, with cheesy foci and cavities.

The bacilli were found in the edges of the cheesy mass, in some instances in its centre. There were many spores, and occasionally bacilli were seen in what was apparently healthy tissue.

No. XX. Tuberculous lung.

This, like the preceding, was a mass of tubercle, with many cheesy foci and much cicatricial tissue.

Bacilli were found, in not very large numbers, near the edges of the more recent degenerations; in much less abundance in the old fibrous portions.

No. XXI. Tuberculosis of kidney.

Bacilli were found in plenty in the contents of a small cavity in the cortex of the kidney, and in the tissue from a nodule near by.

This case had been diagnosed during life as a perinephritic abscess, and a drainage tube had been inserted for almost a year.

No. XXII. Tuberculosis of eye.

This specimen was removed last fall, and had been preserved in chromic acid.

It was only after two attempts, and staining prolonged for forty-eight hours, that a few bacilli were discovered in the nodule.

No. XXIII. Acute miliary tuberculosis in a child.

Bacilli were found in large numbers in the cells in the tuberculous portions of the spleen, of an enlarged cheesy mesenteric gland, and in a tuberculous ulceration of the intestine.

As a result it will be seen that in every case of inoculation tuberculosis was developed, and the microscope revealed the bacillus in some portion of the organs of the animals experimented upon. There are a number of guinea-pigs still under observation. I was able to trace the bacilli with increasing certainty as practice trained my eye for their definition in the tissues. I have found a marked difference in the apparent size of these organisms in the sections examined. In some specimens they appear very fine and delicate, — almost indistinguishable, — sometimes only a line of dots being visible; in most cases they are exceedingly distinct and well marked. However, as they are always of the same size and appearance in the preparations of fluid matter, and as those which appear to be finer and more delicate seem to fade quicker, I am led to believe that the apparent variations in size are due to optical effects from imperfect staining. Some observers obtained their results in the examination of tuberculous tissue by grinding a tubercle in a mortar with water and drying the resultant mass upon cover-glasses in the manner of sputum preparations. The ease of this method is more to be commended than its accuracy, for in an examination of this kind every source of error should be eliminated that it is possible to get rid of.

In February last I began a series of observations of the sputum of a set of phthisical patients, all known to be so by the physical signs. These observations have been continued up to very recently, and the results obtained in five represented in a diagrammatic manner upon the charts. The upper curve represents

CASE II. Sick for one year, hæmoptysis the first symptom.

From February 17th to June 3d fourteen examinations were made, with positive results in thirteen. When bacilli were found at all they always occurred in large numbers. (Vide Chart II.)

CHART II.¹

CASE III. Cough for six months. Gained weight while under observation, and was finally discharged relieved.

From February 17th to April 20th eleven examinations were made, with positive results in six. For five successive examinations no bacilli were seen, and they never occurred in large numbers.

CASE IV. Cough for eight months.

From February 17th to April 20th ten examinations were made, with positive results in nine. The number

CHART III.¹

of bacilli varied very greatly, and the results are tabulated on Chart III.

CASE V. Sick for seven years.

From February 17th to June 3d fifteen examinations of the sputum were made, with positive results in nine; the bacilli always occurred in very small numbers. (Chart IV.)

CASE VI. Sick for three years, hæmoptysis the first sign.

From February 17th to June 6th there were fifteen examinations of the sputum, with positive results in twelve. The bacilli were always very few until the last examination, when the number observed increased

very greatly, but with no corresponding increase in the temperature. For three months this patient's temperature has been sub-normal much of the time. (Chart V.)

CASE VII. Sick one year, hæmoptysis the first sign. From April 20th to June 3d four examinations were

CHART IV.¹

made, and very many bacilli were found in every case. This patient's temperature curve was pretty constantly high.

CASE VIII. Cough for one year.

From May 19th to June 3d three examinations were made, with bacilli in diminishing numbers, the temperature upon the days of the examinations being less each time also.

CASE IX. Cough for two years.

From May 19th to June 3d three examinations were

CHART V.¹

made, with very many bacilli in every case. The temperature, however, showed no exact correspondence.

CASE X. Cough and hæmoptysis for ten years.

From February 17th to June 3d fifteen examinations were made, with positive results in six only, and in these the bacilli were always seen in but very small numbers. The temperature of this patient has been for weeks at a time within half a degree of normal.

CASE XI. This was a case of pleurisy, which was examined for comparison.

From March 14th to May 19th seven examinations were made, with negative results in every case.

A comparison of the charts tends to show that there

¹ For reading see Chart I., preceding page.

is only a very general correspondence between the numbers of the bacilli and the height or variations of the fever line. A large number of bacilli does not necessarily mean a high temperature. The fever curve of each patient varies somewhat, and has a general average of its own, sometimes a very high one and sometimes entirely the opposite. It is with this average range of temperature in the special case that the number of the bacilli must be compared; and it is only by this observation of special cases that the information obtained is of value. It is also shown that a continued examination of the sputum for weeks at a time may be necessary before the absence of the bacilli can be definitely assumed, as is shown in Case V., where six successive examinations were made before they were detected. In rapid cases, with free expectoration, there are enormous numbers of the bacilli to be found. The characteristics of the sputum also seem to be something of a guide to the number of bacilli that one may expect to find. If it is largely mucous, with but a few yellowish nodules in it, bacilli will only be found in these nodules, and then, possibly, only in small numbers. If, however, the sputum be of a more purulent fluid character, the bacilli will probably be present in great numbers whatever portion is examined.

The result of all the work that has been done upon this subject may be summed up as follows:—

I. A staff-shaped micro-organism exists, in all forms of the tuberculous process, and its presence has been demonstrated in them.

II. It is more abundant in the rapid than in the slow forms of the process.

III. Its specific nature as the cause of tuberculosis is claimed by Koch on the ground of his observations.

IV. Its specific character has not been successfully refuted by trustworthy observations.

V. Its value as diagnostic evidence of tuberculosis is very great, although its absence cannot be considered as excluding that process.

The only observer who has thus far attempted the repetition of Koch's cultivation experiments is Professor Feltz,¹ of Nancy, who has announced the complete failure of his work. The manipulation is such, however, that more than one failure must occur to upset the testimony of complete and repeated successes.

THE USE AND ABUSE OF ERGOT.²

BY GEORGE L. WOODS, M. D., OF SPRINGFIELD.

THE object of this paper is to invite attention to the action and therapeutic indications of ergot of rye, more especially in obstetric practice, with some incidental observations upon its possible dangers on the one hand, and its latent resources on the other. Although the use of oxytocics has existed from very remote times, the list of drugs which possess this property in a special degree is very short.

It has been ascribed in varying degrees to borax, cinnamon, tansy, cottonroot bark, cannabis indica, etc., but the leading member of this class which has attained such importance and universal use is undoubtedly ergot of rye, and this very fact, to the mind of the writer,

justifies and calls for our constant study of this powerful agent until we better understand its capacity and resources.

The natural history and general characteristics of spurred rye, and the numerous but unsatisfactory attempts to isolate its active principle which have been made, are familiar to us all, and need not detain us. The phenomena of chronic poisoning, which Trousseau so graphically describes as seen among the peasantry of France, who largely consume ergoted rye as food, we do not see. The symptoms of acute poisoning, which also we seldom see, are, briefly, dilatation of pupils, dimness of vision, frontal headache, giddiness, stupor, collapse, and sometimes partial paraplegia. Dr. E. R. Squibb considers an underfed and semi-scorbutic habit of body essential to the development of poisonous symptoms from the ingestion or administration of ergot.

The presence of ergot in rye flour may be demonstrated in the following manner: Mix a small quantity of the sample with ether, add a few crystals of oxalic acid, boil, and allow the liquid to clear. A red tinge indicates the presence of ergot.

When our countryman, Dr. Stearns, first called attention, in 1807, to the scientific use of ergot as a uterine motor stimulant, its physiological action was but imperfectly understood, and even now eminent authorities can scarcely agree upon more than the one incontrovertible fact, that ergot increases the force and frequency of the contractions of the uterus with a tendency to make them tetanic in character. That it has a similar contractile effect upon all unstriated muscular fibre, which is so generally distributed in the hollow muscular organs, seems equally clear.

Wernich attributes the ecbotic properties of ergot to irritation of the uterine nervous centres, caused by secondary arterial anæmia of the spinal cord, due to loss of tone in, and dilatation of, the veins.

Kohler refers the contractions to increased irritability of the peripheral nerves in conjunction with spinal anæmia.

A committee on therapeutics in the Chicago Society of Physicians and Surgeons recently reported that ergot excites activity of cardiac inhibitory centres, and also the vaso-motor nervous centre in the medulla, thereby slowing the heart's action, causing contraction of the arterioles, increase of blood pressure, diminution of blood supply, and predisposing to death of the extremities. Very large doses then would seem to have a paralyzing effect upon the heart.

A knowledge of the physiological action of drugs is generally essential to their judicious administration. The most prominent action and use of a drug should not engage our attention to the exclusion of other occasional but deplorable effects. We should remember that quinine is not only our closest approximation to a specific in ague, but that in certain cases and conditions it works an irreparable injury to the organ of hearing, and that an ecbotic effect upon the gravid uterus has been directly caused by its careless and routine exhibition. So in the use of ergot, every consideration of professional honor, success in practice, and safety of our patients, requires of us an abiding consciousness that we are using a double-edged sword, potent not only to stimulate a flagging uterus, but equally capable in careless hands of destroying valuable life, and mortally wounding a professional reputation. But however interesting and instructive it might

¹ Feltz, Gazette Hebdomadaire, March 2, 1873.

² Read at the annual meeting of the Massachusetts Medical Society, June 12, 1883, and recommended for publication by the Society.

be to know precisely how the nervous, circulatory, and muscular systems are influenced by ergot enough may now be learned by the obstetrician to insure its safe employment.

When we reflect upon the extensive, indiscriminate, and unscientific use of this potent agent by ignorant empirics long before its recognition by the profession, we may well question whether more harm than good did not result. Seventy-five years ago, when it was first introduced, medical science was embryonic as compared with its grand proportions of to-day; the investigation of new remedies was not then a daily occurrence. The drug had to wait long years before its constituents were demonstrated by analysis and it became established in popular favor. The earlier writers give meagre and careless directions for its use,¹ and discredit the occasional reports of its deleterious influence upon the fœtus which were made thus early. However presumptuous it may appear to criticize the medical teaching of the past fifty years, a certain independence of thought and action is justifiable. It is thus that our science progresses. In proportion as we break away from the traditional and plunge into the experimental do we confirm and establish existing theories or discard and supplant them with those which are new and progressive. Because our text-books have always taught that with certain precautions ergot is innocuous in tardy labor we are not obliged to accept the statement as a fact if it can be shown at present or in future that its use has not been sufficiently restricted. That such has been and even now is the case is the firm conviction of the writer.

The use of ergot in the first stage of labor is not to be mentioned in this presence.

In view of the instruction which the average graduate has received, and the fact that he enters upon the practice of obstetrics without having seen a case of labor, but with an indefinite idea that ergot is a harmless time and labor saving drug, its employment in the second stage of labor becomes a radically different matter. Abundant authority for this use, however, is attested. The indications usually given, which present such a remarkably stereotyped appearance in every succeeding work on obstetrics as to preclude in the mind of the student the possibility of any other views being entertained, may be tersely stated as follows: In lingering labor from uterine inertia it is regarded as essential that the presentation be vertex, the cervix well dilated, the perinæum and ostium vaginæ relaxed, and that there be no fœtal or pelvic deformity or other obstruction to the speedy delivery of the child. The contra-indications as given naturally suggest themselves, but it is the main object of this paper to express the belief of the writer, who never gives ergot at this stage of labor, but uses the forceps instead, that our authorities have been too liberal in their indications; that the contra-indications and dangers have not been fully appreciated or enumerated with sufficient fullness and clearness; that the routine administration of ergot, into which some of us fall, has been productive of great harm; and, finally, to urge its greatly restricted use.

As employed by intelligent physicians to-day rupture of the uterus is doubtless a remote danger to the mother, but if we only had access to Clay's Hand-Book of Obstetric Surgery, and gave ergot when the os uteri became dilated to about the size of half a crown, as therein directed, the prospect of a lacerated cervix

would be exceptionally good. The approximately uninterrupted pressure of the head upon an incompletely dilated os is well calculated to bring about this untoward result. Clay is evidently prejudiced in favor of ergot, for he allows its moderate use in primiparæ, and bids for distinction in connection with its introduction to British obstetric practice.

Rupture of the perinæum is an accident, irrespective of the use of ergot, which is occasionally unavoidable. The wonderful power of the uterine contractions under the influence of ergot is best appreciated by those whose hands have been subjected to the pressure. In proportion as ergot is used does the distention of the perinæum become unmanageable, and the liability to its serious injury increase. Too little attention is paid to the fact that in lingering labor the maternal passages are hot and dry, and unprepared for the rapid and forcible expulsion of the child. More or fewer abrasions of the mucous lining cannot fail to occur, over which the lochia must flow, and through which septic matter may be absorbed into the circulation of the mother, and prejudice her chances of recovery, while lacerations of the cervix generally escape detection until long afterwards, when their ultimate effects have impelled her to consult her physician.

The writer feels that he cannot too strongly urge the importance of withholding ergot during the entire period of dilatation and subsequent expulsion of the child. Exceptions will be taken to this total prohibition by men of experience who claim immunity from accident. Granting that these claims are sometimes well founded, the facts yet remain that ergot is daily given before the cervix is fully dilated; that rigidity and laceration often follow the sudden and continuous impingement of the head upon it; that the drug is often and repeatedly given to save time or through deference to the wishes of the patient, and before any disproportion of diameters can be accurately ascertained. The gauntlet of impaction, the forcible passage of a large head through a small pelvis, pelvic phlegmasiæ, sloughing, septic absorption, etc., must inevitably be run.

In view of all this and more which might be pointed out did time serve, we are confronted by this question, Do the benefits arising from this use of ergot compensate for the risks incurred? But little notice has yet been taken of idiosyncrasy. In one case the writer has seen the ordinary symptoms of collapse follow the use of a moderate dose of ergot before delivery of the placenta, accompanied by a tonic contraction at the neck of the uterus, which effectually prevented its accomplishment for several hours. Within a few years several similar cases have been reported in the journals, but whether this is an important factor in the production of the deplorable results sometimes following the exhibition of ergot requires further demonstration.

Considering the action of ergot upon the circulatory system, an enfeebled or diseased heart would appear to be a contra-indication to its use which is universally ignored. Cazeaux emphasizes the dangers to the mother, while Schröder argues that the persistent contraction of the uterus induced does not materially aid the dilatation of the soft parts, and disputes its efficacy as an expulsive agent. Barnes bears testimony to the unreliability of ergot, and its tendency to add to the already existing depression of the patient. Men of large observation and experience assert that ergot is

¹ Eberle, *Mat. Med.*, 1825.

treacherous if used to prevent impending hæmorrhage, and that the exhausted condition of the uterus which succeeds such violent contractions sometimes predisposes to the emergency feared. Meigs does not give ergot for its expulsive effect, but prefers the forceps. Though abuse may grow out of the use of the forceps as well as of ergot their employment presents marked advantages over the latter. A case which is suitable for ergot admits of their application; the liability to lacerations is materially lessened; the progress of the child is under control; the risk of asphyxia is obviated, and its safety is assured.

The danger to the child under the use of ergot can no longer be underestimated. Whether a poisonous effect is produced, as has been claimed, cannot yet be definitely stated, but the tendency to tetanic contractions with prolonged pressure upon the placenta or funis seriously interferes with the oxidation and decarbonization of the foetal blood, and imperils the life of the child. If Churchill¹ be followed, who allows ergot to be given when the breech presents, how can this danger fail to be materially increased when the placenta is firmly compressed between the unyielding head and the uterine wall?

Spiegelberg insists upon the necessity of carefully observing the foetal heart after the use of ergot, in order that the forceps may be immediately resorted to in threatened asphyxia. That this is often done may well be doubted. Benicke reports twenty-seven cases in which ergot was given during the second stage on account of uterine inertia. Spontaneous delivery occurred in but seven of these cases. It should be axiomatic with every practitioner that economy of his own time never justifies the use of ergot, but beyond every private and selfish consideration he cannot escape the responsibility imposed by a knowledge of its unreliability, its manifold dangers, and the frequent necessity for instrumental interference.

The routine practice of many physicians of giving a drachm of ergot as soon as the head is born is also open to objection. It sometimes locks up the placenta so tightly that only time, chloroform, or nitrite of amyl will release it. Personal observation leads the writer to this conclusion, although practitioners of much larger experience doubt its possibility, asserting that it has never occurred to them. This contingency, however, has long been recognized. An author, writing so long ago as 1835, says: "An overdose of ergot may produce such contractions of the uterus after delivery as to cause retention of placenta." To show that this is not an antiquated thing which has long been exploded, we may quote from so recent an author as Lusk, who takes advanced ground and represents a growing sentiment against the routine and indiscriminate use of this agent.

After prohibiting its use in the second stage of labor, except as a prophylactic against post-partum hæmorrhage, he says: "The only imperative use of ergot is in post-partum hæmorrhage, resulting from uterine atony; but even then it should be withheld until after the expulsion of the placenta, lest the uniform uterine contractions lead to its prolonged retention or interfere with manual efforts for its extraction."

Because of this peculiarity in the action of ergot it cannot be relied upon in the management of abortions and miscarriages. It is after the uterus has been completely emptied of its contents, and for a varying de-

gree of time after delivery, then, that ergot, in the opinion of the writer, meets its proper and strongest indication. No physician should attend a case of labor without having ready to hand hot water and a solution of ergotine, with appropriate syringes prepared for instant use, should hæmorrhage occur after complete evacuation of the uterus. Post-partum hæmorrhage is thus robbed of half its terrors.

One of the most frequent indications for the use of ergot is subinvolution of the uterus. It has long seemed to the writer that appropriate prophylactic treatment, provided it could be applied, would greatly reduce the number of these cases. This treatment, which is found to be impracticable without the hearty coöperation of the patient, should begin from the moment the third stage of labor is completed. At this time, when the uterus has thrown off the burden which it has carried for nine months, the organ weighs, according to Heschl, from twenty-two to twenty-four ounces; and its length, according to Bömer, who has measured in sixty-four cases, averages a little more than six inches. Hewitt gives the length as eight inches. At the end of the first week, at which time women often get up, the uterus weighs from nineteen to twenty-one ounces; at the end of the second week, from ten to eleven ounces; at the end of the third week, from five to seven ounces, and the nearest possible approach to the normal weight of about two ounces is not reached until the close of the second month. The new mucous lining of the organ does not form before the third week. We must dissent, then, from the views of an eminent writer, if, as reported, he advocates the encouragement of the patient to rise and dress on the third or fourth day after delivery in ordinary cases. The writer ventures the opinion that this time for keeping the bed or lounge is much too short. Indeed, the time-honored period of nine days does not seem long enough. At this time, even, although the bulk of the uterus is considerably reduced, we have seen that it yet remains enlarged, soft, congested, and too heavy for its relaxed supports. Walking, standing, lifting, pelvic inflammations, etc., contribute to retard the process of involution, in many cases entirely arresting it short of completion, when we have resulting the condition of subinvolution, the grand predisposing cause of that long train of symptoms so familiar to the physician. Have we not here a clear indication for prophylaxis?

The patient should not only be kept longer in bed to facilitate involution, but we shall do well to remember that it is the soft, spongy, subinvolved uterus for which Bartholow recommends ergot. Believing that the process of involution is materially aided and advanced by the cautious use of ergot, it is the practice of the writer to give it in moderate doses for some days after delivery. Corroborative evidence of the value of this plan of treatment is not yet abundant, but Dr. Garrigues, of New York, may be quoted upon the use of ergot as follows: "Ergot ought never to be given during labor. I use this drug in every labor, but not until after the placenta has been expelled. I give it even for four or five days, because I think that by causing contraction of the muscular coat of the blood-vessels it counteracts absorption of septic matter, and by increasing uterine contraction insures good involution." The abuse of the use of ergot is by no means confined to the profession.

The late William Warren Greene once urged upon

¹ System of Midwifery.

a class of students the propriety of using the simplest language with their patients, but recommended the invariable employment of scientific language among themselves. Some exceptions might reasonably be taken to the first injunction. We should all realize the wide-spread tendency to escape the dangers and responsibilities of maternity. Women are in constant temptation to seek means and use them privately to accomplish their object. Frequently we find them in the cities using ergot with the avowed intention of procuring an abortion. To all inquiries, from whatever source, concerning the nature and effects of ergot guarded answers should be given,—not necessarily false, but calculated to divert the mind from its ebolic properties, and the botanical name only should invariably be given, as less likely to be remembered than the common one.

The unreliability of ergot has caused great annoyance. Camphor prevents much deterioration of the powder, but a fresh preparation is more reliable. The addition of one per cent. of acetic acid renders the liquid preparation permanent.

As it is sometimes desirable to give ergotine for several weeks in succession, it becomes not only an interesting but important question as to how long the remedy can be given with safety. Doubtless no fixed rule can be laid down; but as some evidence can be advanced to show that ergotine has a cumulative effect upon the system, prudence would seem to dictate conservatism.

At a meeting of a medical society in Paris some time since Dr. Boissarie called attention to the possible dangers attending the prolonged administration of ergotine by the mouth. He detailed the case of a young woman of twenty-five, with albuminuria, who took a daily dose of two centigrammes of ergotine for four weeks. About a month after cessation of treatment gangrene developed in both inferior extremities.

Dujardin-Beaumetz relates a case of enteric fever in which gangrene supervened after the exhibition of a daily dose of one gramme of ergot for one month. A case of pulmonary gangrene in a child of thirteen years has also been reported. Ergotine, in a daily dose of two centigrammes, was given by the mouth for about two months for incontinence of urine. Fatal hæmorrhage occurred within a month after cessation of treatment.

Dr. Lusk, of New York, reports a case of fibromyoma of the uterus treated by ergotine injections into the subcutaneous tissue of the abdomen over the tumor. The bulk of the growth was rapidly reduced, but at the expense of gangrene of the compressed tumor and fatal septicæmia.

CEREBRAL ERYSIPELAS.¹

BY AUGUSTUS P. CLARKE, M. D. (HARV.)

I was called Thursday, March 10, 1881, to visit S. P. S., aged fifty-one years, who was then suffering from severe headache. The pain complained of was on top of the head. There was some soreness of the throat, probably from swelling and tenderness of the lymphatic glands of the neck. There was no pain in deglutition. The pulse was 110 per minute; the temperature was 102.2° F. There was some swelling

about the nose, which was red, and hot, and painful. The face, and ears, and scalp were also affected. The patient, the night before, had suffered from the effects of a severe chill, and at the time of my visit he complained of being chilly, or, rather, preferred to be in a warm room. Tongue coated. There was very little nausea, but no vomiting. The cold evidently appeared to be an acute attack of erysipelas. The patient was a tall and rather stout man. Hair turned gray. Recently he had been employed as a private policeman for night service, but on returning home in the morning was unable to obtain sufficient sleep; the rooms of his apartment or dwelling were too much crowded for quietness necessary for good sleep. He had from time to time suffered with some trouble with his stomach; was somewhat dyspeptic, and had occasionally complained of uneasy sensations in the cardiac region, but nothing serious was apprehended by himself or friends. At the time I was called he had had no movement of the bowels for some two days, so I prescribed saline laxatives and refrigerating drinks; also prescribed ung. petrolei and boracic acid, four grammes of the latter to thirty-two of the former, to be applied to the swollen parts of the face. Next morning, the 11th, patient wrote me a note in regard to his condition. He stated that the saline mixture had operated but slightly, but that he thought he was "a little better." He asked whether he should continue the saline aperient. He was up and around the house somewhat during the day; he also rested on a lounge in his sitting room. While reclining on the lounge about twenty minutes of seven P. M., the 11th, he was noticed, on a sudden, to be convulsed, that is, "his mouth was drawn to one side," as an attendant remarked who stood near him at the time, and he immediately began to snore with slow and irregular respiration; he was unconscious, and appeared to be in a dying condition. I was at once sent for, and I reached his house twenty minutes past seven, when the patient was evidently dead. The pupils were widely dilated, the eyes fixed. There was no action of the heart; hands cold, and face on left side becoming purple. There had been erysipelas in his family some three months before. His daughter then suffered from a severe attack of erysipelas of the face and head.

Autopsy of the body of S. at four P. M., the 12th. Present Drs. Holt, Clarke, Dow, and Bryant. Rigor mortis well marked. Body well nourished and developed. The head was first opened. No marked adhesion between the cranium and dura mater. The vessels of the pia mater were of a bright-red color, so much so as to be especially remarked by all. The vessels of the pia were somewhat injected. On removing brain no clot was found in it. The vessels at the base and other parts appeared similar to the others just described. There was no embolus nor thrombosis in any vessel of that organ. There was no softening nor anemia from the presence of emboli of the carotid or other artery or vessel. There was, however, some serum under the arachnoid (more than normal). The lungs, liver, kidneys, and spleen were all heavily engorged with dark blood. The heart was pale, and perhaps a little softer than normal, and fatty; the valves were healthy, and seemed capable of further duty. The stomach and duodenum on opening were darker than normal, though no ulcers were observed. There was a great amount of fat deposited about the intestines and omentum. The abdominal parietes were very thick

¹ Read before the Cambridge Society for Medical Improvement, February 27, 1882.

with fatty tissue. Neither the œsophagus nor the stomach nor duodenum exhibited any traces of corrosive or irritant substances which had acted on these parts. The sudden death must have been in consequence of the gradual accumulation of serum under the arachnoid. This must have taken place during Thursday and Friday, and after reaching a certain quantity, in connection with a feeble heart (fatty) and an altered condition of the blood on the nervous centres, immediately arrested the functions of the brain.

J. Russell Reynolds, F. R. S., in his *System of Medicine*, under the heading of Prognosis of Erysipelas, thus remarks: "In some instances there are symptoms of 'meningitis' observed during life, and evidences of its presence and its results may be discovered after death, but in others the cerebral symptoms are those of oppression rather than excitement, and the post-mortem appearances are those of effusion only, or of that embolic occlusion of vessels described by Dr. Bastian. In the latter class of cases the symptoms are probably due partly to the direct effect of altered blood upon the nervous centres, and also to the indirect effect of that alteration in leading to possible effusion or unobstructed circulation." In the case reported there was no evidence of "meningitis," nor were there any evidences of embolic occlusion whatever, only a very limited amount of effusion beneath arachnoid. The revelations made by the autopsy were rather negative than otherwise. During life there were no marked symptoms of oppression as referred to by the author above cited, nor were there any very marked ones of excitement. The pulse was only 110 and full, and the temperature not above 102.2° F. at the time of my visit. Watson, in his *Lectures on the Practice of Physic*, remarks that erysipelas may prove fatal "by effusion within the head and coma." He also remarks that the patient may die of apnoea, sometimes almost suddenly, unexpectedly. The solution of the mystery may be discovered sometimes by examining the throat, when the submucous tissue of the glottis or epiglottis will be found filled with serum or pus, and the chink of the larynx being nearly or completely closed. But on examining the œsophagus for the effects of irritant poisons in the case reported no such appearances were observed either in the throat or in the submucous of the larynx or glottis. Many authors remark that where erysipelas of the face and scalp occur inflammation of the membranes of the brain is liable to be produced, and that coma may follow the supervention of serous effusion within the cranium. In vol. xci. (1874) of the *Boston Medical and Surgical Journal* Dr. J. C. Gleason, of Rockland, Mass., says: "In the large proportion of fatal cases (of erysipelas) death is owing to failure of the vital powers as a result not of the inflammation, but of a true blood poisoning by morbid atoms, the toxic character of which is not yet fully known." He conjectures that the principle of the contagium or infection acts as a ferment, as in other zymotic diseases, and that it is a catalytic agent capable of inducing changes or alteration in the composition of the blood. Holmes, in his *System of Surgery*, vol. i., under Prognosis of Erysipelas, remarks: "It is in the head and in the limbs that injuries most tend to excite the inflammation. In the head it is most specially liable to occur both symptomatically and idiopathically, and should never be regarded otherwise than as a serious disease from the disposition which exists to congestion of the membranes of the brain,

and to spreading inflammation in the fauces and air-passages."

Huguenin, in Ziemssen's *Cyclopædia of the Practice of Medicine*, vol. xii., p. 453, speaking of hyperæmia as an affection of the pia mater, and "inflammations about the head," observes, that "erysipelas may be taken as the prototype of this class. Headache, mental confusion, excitement, anxiety, photophobia are the symptoms of the cerebral fluxion usually observed, and they may become very intense. Delirium of every variety and every degree of intensity may occur, and the restlessness may gradually change into coma, while the temperature often ranges quite high. Some may attribute this termination to the elevated temperature alone; usually cerebral hyperæmia is the only lesion found, but we are convinced that accurate observation will in the future demonstrate more essential anatomical changes." In a foot-note a case is mentioned "where death occurred with the above-mentioned symptoms, the pia mater was perfectly normal, but migration and a small extravasation of white blood corpuscles were found in the white substances of the hemispheres, exactly like what is seen in certain stages of dementia paralytica." The same author states that "the congestion of erysipelas does not terminate in a purulent meningitis. The meningitis of the convexity, which not infrequently complicates erysipelas, we believe to be metastasis, and have only observed it where there was suppuration." Huguenin fails to mention the occurrence of effusion under the arachnoid and its gradual accumulation within the cranium. But he refers the termination of the case to the elevated temperature and to cerebral hyperæmia, and to the migration and extravasation of white blood corpuscles found in the white substance of the hemispheres. In the case reported the temperature was not greatly elevated, nor was the hyperæmia very marked.

Niemeyer, in his text-book of *Practical Medicine*, vol. ii., p. 416, says: "Erysipelas is sometimes complicated with intestinal or with bronchial catarrh, sometimes with intense hyperæmia of the kidneys, and with catarrhal or croupous inflammation of the uriniferous tubules. A far more serious but less common complication is the extension of the inflammation from the scalp to the meninges. The so-called 'striking in' of the erysipelas is a consequence of the malignant character of the disease, and of incipient collapse, and is not to be regarded as the cause."

Da Costa, in his *Medical Diagnosis* (second edition), page 723, speaking of erysipelas, says: "In some cases the inflammation extends to the brain, and instead of the wandering at night, always a very common symptom, we have violent delirium, soon succeeded by coma and rapid sinking. In other cases, again, and they are generally very bad ones, we may find these active cerebral symptoms, and yet not be able to detect after death signs of inflammation in the brain or its membranes."

Tanner, in his *Practice of Medicine*, page 288, states that "erysipelas now and then proves fatal by the extension of the inflammation to the brain or its membranes, giving rise to effusion and coma." He also states that the failure of the vital powers may be a cause of death in such cases." In the *Medical and Surgical History of the Late War*, Part I., Surgical Volume, pages 77 and 101 and 185, mention is made of erysipelas as occurring in gunshot scalp wounds and

contusions of the cranial bones and gunshot depressed fractures of the skull. Such complication was, however, comparatively rare, as there are only three such cases reported in the 363 cases of depressed gunshot fractures of the skull. Only twenty-two cases of erysipelas supervening after gunshot wounds limited to the integuments of the cranium are reported; eight of these terminated fatally. The precise features of these secondary complications are not reported. The author of this great work infers from the prescriptions used that meningitis or some form of encephalitis must have supervened that induced the fatal results. This is very doubtful, as the autopsy of but one case is mentioned, and the report only states that "the liver, spleen, and mesenteric glands were found enlarged."

Aitken, in his *Science and Practice of Medicine*, vol. i., p. 339, says that: "Extension of the inflammation to the membranes of the brain sometimes takes place, while the external inflammation continues. This untoward event is followed by delirium and coma. But delirium frequently supervenes in the course of erysipelatos attacks, independently of any metastasis or extension of the disease to the membranes of the brain." He also says fatal cases terminate by coma, and with dissipated habits, or in dilapidated constitutions, the delirium resembles that of delirium tremens not due to inflammation of the brain, but in consequence of an altered condition of the blood and of the nervous system." He cites Barclay in support of this last remark. It will also be remembered in the case reported that there was no marked delirium resembling that of mania à potu, and positively there was no coma. The death was sudden and unexpected, just as Watson says a case may so terminate, though not by apnoea, which is sometimes the cause, according to this last authority. The patient formerly had been of irregular habits, and his constitution had greatly been impaired. As nearly all authorities agree that an altered condition of the blood by certain morbid or toxic atoms is always an important factor in such cases, it seems but reasonable to infer that the sudden death must have been due, as said before, to the gradual accumulation of serum under the arachnoid. This must have been going on during Thursday and Friday, and after attaining to a certain quantity, in connection with a feeble heart and an altered state of the blood, immediately arrested the functions of the brain.

SURGICAL TREATMENT OF HOPELESS CASES OF MASTURBATION AND NOCTURNAL EMISSIONS.

BY TIMOTHY HAYNES, M. D., CONCORD, N. H.

LIKE many others in general practice I am frequently called upon to care for the victims of self-abuse.

While I always strive to help this perverted state of the mind by advice and treatment, by counseling marriage, perhaps, and at times even the immorality of a mistress, still there are cases so utterly desperate, so destroyed mentally and physically, that I have been led to face the question, Cannot help be given at the expense of the procreative powers?

The scar of castration is a stigma.

It was with a view of avoiding this deformity that I was led to remove parts of the spermatic ducts in place

of the testicles. The operation, which was the same in all three cases reported below, was as follows:—

An incision midway between the external inguinal ring and the testis laid bare the duct, from which a half inch was resected, and the slight wound closed by sutures.

CASE I. E., aged eighteen, a confirmed masturbator, was admitted to the New Hampshire Asylum for the Insane September 4, 1843, and discharged relieved the 25th of March following.

Readmitted July 2, 1845, and discharged October 2d.

His condition seemed to be beyond medical aid, and I was asked to see him to consider the feasibility of castration. I advised resection of the duct, which was assented to, and I did the operation according to the above method.

The patient, living in a distant part of the State, passed out from under my own observation after the operation. From others I learn that while he never fully recovered from his demented state, still he was so far relieved by the treatment that he became a very useful farm hand.

He died in 1881.

CASE II. Mr. L., aged thirty-six, had been addicted to masturbation and had suffered from nocturnal emissions for several years. His mind was so disordered as to render him totally unfit for any business. Starting on a journey, he was more than likely to turn up miles from the place he intended to reach.

I operated March 21, 1872. This patient lives near me, and has been kept under observation.

Soon after the operation he began to improve in flesh and strength, and is now a correct, healthy business man. His testicles are normal as to size and appearance, but the sexual desire is entirely destroyed.

CASE III. I was called July 27, 1878, in consultation to see Mr. S., aged thirty, who had practiced self-abuse for years, suffered from nocturnal emissions, and was such a physical wreck that he was unable even to walk without assistance.

When seen he was much emaciated, and had been confined to his room for months. While he could hardly be classed as insane, still his mind was evidently impaired, and at times it was difficult to get him to take sufficient food.

I resected the ducts, and learn from his physician that he improved greatly in flesh and strength after the operation.

He died February 22, 1882, without medical attendance.

By this simple operation, leaving behind it no deformity of the genitals, we have succeeded in all three cases in improving the mental and physical condition of our patients, while the sexual appetite was as effectually destroyed as by castration.

RECENT PROGRESS IN MEDICAL CHEMISTRY.

BY WILLIAM B. HILLS, M. D.

SYNTHESIS OF URIC ACID.

M. HORBACZEWSKI¹ has prepared uric acid synthetically in the following manner: Pure glycochol was finely pulverized and mixed with ten times its weight of pure urea, prepared from ammonium cyanate, and

¹ Journal de Pharmacie et de Chimie, January, 1883, page 70, from Berichte der Deutschen Chemischen Gesellschaft, 1882, page 2678.

the mixture heated in a flask placed in a metal bath at 200° C. to 230° C., till the liquid, which was at first clear and colorless, became thick, turbid, and brownish-yellow. The resulting product when cold was dissolved in dilute potassium hydrate, and, after supersaturation with ammonium chloride, was precipitated with a mixture of ammoniacal silver solution and magnesia mixture. The precipitate thus obtained was washed with water containing ammonium hydrate, and decomposed with potassium sulphide. The silver sulphide was removed by filtration, and the filtrate, after acidulation with hydrochloric acid, was concentrated on a water-bath. The crude uric acid thus separated was purified by familiar methods, whereby finally a yellowish crystalline powder was obtained, exhibiting the same crystalline form, the same elementary composition, and the same reactions which are characteristic of the uric acid obtained from urine.

PARAXANTHINE.

G. Salomon¹ describes the method of extraction and the properties of a new constituent of normal human urine to which he has given the name "Paraxanthine." It is distinguished from guanine, xanthine, and hypoxanthine by its reaction with sodium or potassium hydrate. The addition of either of these reagents to a concentrated solution of paraxanthine produces a crystalline precipitate, which dissolves on the addition of warm water, but separates out again when the liquid cools.

GENESIS OF PTOMAINES.²

These bases were originally regarded by Selmi, and afterwards by Schwanert, as exclusively products of cadaveric putrefaction. Selmi, however, afterwards modified his opinion so far as to admit that, in cases of serious pathological alterations, they might be produced in the animal organism during life, a conclusion fully confirmed by Spica. Finally the question was further modified by the experiments of Paternò and Spica on blood and on egg-albumen, and by those of Gautier on normal urine, all of which showed that reactions similar to those above alluded to may be exhibited by perfectly healthy animal fluids.

To throw further light on this question Coppola has made a series of experiments on the physiological action of bases extracted from the blood of a healthy dog; and his conclusions are that alkaloids extracted from healthy animal fluids, carefully protected from putrefactive alteration, may exhibit strong toxic properties, and that consequently whatever idea may be formed of the nature of the putrefactive process, the albuminoids must be capable of undergoing certain transformations, which may give rise to the formation of poisonous alkaloids. This being the case, it becomes a question whether among these transformations should be included those which albuminoidal substances undoubtedly undergo in the extraction of alkaloids by Dragendorff's process; for if this be the case, it might be alleged that the ptomaines are merely products of the decomposition of the albuminoids, brought about either by chemical reagents or by putrefaction, either during life or after death; and until some process of extraction shall have been devised in-

capable in itself of giving rise to the production of such alkaloids, no satisfactory proof can be given of their presence in the normal animal organism.

Coppola, in continuing his experiments on this subject, arrives at the following conclusions:—

(1.) Arterial blood in its normal state does not contain any substance of alkaloidal nature.

(2.) In the decompositions which albuminoids undergo during the process of extraction by the methods of Dragendorff and of Stas-Otto, toxic principles are formed which exhibit the reactions of alkaloids. These conclusions throw great doubt on all experiments hitherto made on the genesis of ptomaines, since the extraction of these bodies either from cadaveric substances or putrefaction products, or from liquids pathological or physiological, is always effected by one or other of these processes, or by some method chemically equivalent thereto. Moreover it is impossible to say how far the formation of such products is influenced by putrefaction, cadaveric or ordinary; and, indeed, notwithstanding the conclusions of Gautier and Étard (who extracted, from putrid animal matter, two liquid alkaloids) it may even be regarded as doubtful whether putrefaction alone is capable of giving rise to the production of ptomaines.

STRYCHNIA.

Dr. J. Kratter³ has made a number of experiments to determine the manner in which strychnia is excreted from the body, and if it is chemically decomposed or not. The results of these experiments are as follows. Strychnia, no matter how introduced, is rapidly absorbed and excreted, totally unaltered, by the urine. The excretion begins within the first hour after the introduction of the drug into the system, and is ended, latest, within forty-eight hours, when the last trace of the whole dose can be demonstrated in the urine. The idea of some that strychnia is deposited in the liver is not tenable, neither is it probable. Any accumulative action may be explained by the fact that a new irritant acts on the nerve centres, the former irritation of which has not totally ceased and equilibrium not having been reestablished, before another dose disturbs it anew.

Mr. Mecredy⁴ relates a very interesting case of strychnia poisoning in which the symptoms were delayed eight hours by opium. The patient, a stout, healthy-looking, well-developed woman of twenty-three years of age, and in the sixth month of pregnancy, took, according to her own statement, a packet of Battle's vermin-killer and immediately thereafter two ounces of laudanum. Four hours later she was first seen by Mr. Mecredy, and was then unable to stand without assistance, or to give any further account of herself than that she had taken poison with suicidal intent. Her face was pale and ghastly, and she presented in every respect the appearance of one suffering from opium poisoning, with the exception that the pupils were little, if at all, contracted. Copious emesis was induced by the free administration of zinc sulphate, and maintained by draughts of hot water, coffee, and mustard-and-water. The vomited matters consisted of fruit, and had only slightly the odor of opium. Symptoms of strychnia poisoning did not begin till four hours after

⁴ Edinburgh Medical Journal, February, 1883, page 757, from the Lancet, 1882, vol. ii., page 724.

the patient was first under medical observation, and eight hours after the dose had been taken. The symptoms, which were greatly obscured by the effects of the opium, were at first slight, being in the form of clonic movements of the hands and in a lesser degree of the feet. Later they increased in extent and degree, extending to the arms, shoulders, and legs, accompanied by slight opisthotonos and considerable pain at the pit of the stomach, but with no trismus, and with but little twitching of the muscles of the face. Four hours after the twitching had begun forty grains of chloral were given, and an hour later, when the symptoms of the opium had greatly disappeared, thirty grains of chloral were given, and a like amount every hour for three hours. The symptoms of strychnia reached their maximum five hours after their commencement, and had almost completely disappeared five hours later; the patient being thus almost well within eighteen hours from the time of taking the vermin-killer and laudanum.

Mr. Mecredy estimates the quantity of strychnia taken at a grain and a half, and calls attention to the delay in the appearance of the symptoms, and to the antagonism between strychnia and opium; the former preventing the contraction of the pupils, and the latter neutralizing, for a time at least, the effects of strychnia on the cord. In conclusion, the practical bearing of the case is alluded to, — opium being recommended for use more freely than is now the custom in cases of strychnia poisoning when chloral and the other usual antidotes are not at hand.

[It is well known that the effects of strychnia may be much modified by the presence of opium. A case is recorded¹ in which three grains of strychnia and one drachm of opium were taken and no serious symptoms appeared for nearly twelve hours; death taking place forty hours after the mixture was taken. Mr. Mecredy's case is considered worthy of a notice in this report because it is only by a comparison of well-authenticated and carefully reported cases that we can learn how far the ordinary symptoms of one poison may be modified by the presence of other substances. — REP.]

ARSENIC.

M. Garnier² has investigated the question of the localization of arsenic in various organs and tissues, and has arrived at the conclusion, from his own experiments, that the liver is the organ in which the poison accumulates to the greatest amount in both acute and chronic arsenical poisoning. Relatively small quantities could be extracted from the brain when large quantities were obtained from the liver.

METHODS OF DETECTING LEAD, SILVER, AND MERCURY IN THE BODY IN CASES OF POISONING.

V. Lehmann,³ after discussing the literature of the subject, describes a series of quantitative experiments in which the delicacy of various processes which have been employed for the detection of these metals is put to the test.

As regards lead, the sensitiveness of certain reagents was in the first place determined. Sulphureted hy-

drogen in alkaline solutions proved the most delicate reagent, giving a precipitate with one part of lead nitrate in ten million parts of water.

In the examination of the organs of the body and of organic fluids, such as urine, it is necessary first to destroy all organic matters by hydrochloric acid and potassium chlorate, otherwise the separation of lead takes place incompletely or even not at all.

In the separation of lead in this way electrolysis yielded results as favorable as those obtained with sulphuretted hydrogen. The method employed was to place the solutions freed from organic matter and acidulated with hydrochloric acid in a bell-jar, closed below by means of parchment paper, and placed in very dilute sulphuric acid. The positive electrode from a battery of three small copper-zinc couples dipped into the solution lying on the parchment diaphragm, on the other side of which lies the negative electrode. Both electrodes were of platinum foil. After twenty-four hours the lead deposited upon the positive electrode was dissolved by boiling with dilute nitric acid, the solution evaporated to dryness, and the residue redissolved in water with addition of sodium hydrate. It was then tested by sulphureted hydrogen in the usual way. For the quantitative determination of lead under these circumstances Lehmann adopts the colorimetric method of G. Bischoff, using sulphureted hydrogen in an alkaline solution.

After the administration of salts of lead the metal may be detected in the urine and all organs of the body. In the case of rabbits to which lead had been given in doses of three to four milligrammes daily traces of it were found in the urine after the first day. The greater portion of the lead is deposited in the tissues, and after four or five days, while mere traces are discernible in the blood, large quantities are found in the heart, lungs, kidneys, brain, and bones.

For silver hydrochloric acid is the most sensitive test. The separation of silver by hydrochloric acid from solutions containing salts and organic matters is not complete, as, for instance, from the urine which holds alkaline chlorides in solution, these latter dissolving in part silver chloride. In such cases and in the organs of the body organic matters must first be destroyed by fusion with potassium nitrate and sodium hydrate. From the residue left after extracting the salts by water the reduced silver is dissolved in nitric acid, filtered, evaporated, redissolved in water, and precipitated by hydrochloric acid. Other methods of determining silver give unsatisfactory results. By the above method silver was detected in sixty cubic centimetres of the urine of a rabbit, under the skin of which eighteen milligrammes of silver nitrate had been injected. Similarly, after subcutaneous injection in eight dogs of forty-eight milligrammes, silver was detected in the urine and liver.

Mercury is found in cases of poisoning in all the tissues and secretions of the body. The author considers the methods of Schneider and of A. Mayer as alone yielding accurate results. In Schneider's method the substance under examination is freed from organic matters by means of potassium chlorate and hydrochloric acid, and the filtrate subjected to electrolysis, the mercury being best deposited on a gold electrode, which Lehmann found to give more sensitive results than copper. The deposited mercury is then converted into iodide, for which purpose the electrode is introduced into a glass tube drawn out in a capillary bore

¹ Wormley's *Micro-Chemistry of Poisons*, page 40, from *Chicago Medical Journal*, November, 1880.

² *The London Medical Record*, June 15, 1883, page 243, from *Ann. d'Hygiène*, vol. ix., p. 310.

³ *Journal of the Chemical Society*, London, 1883, page 687, from *Zeitschrift für Physiologische Chemie*, vi., pages 1-42.

at one end, and sealed at the other. The latter part being heated the resulting sublimate is driven into the capillary portion, which with a bulb-shaped part of the wide tube is then cut off before the blowpipe. This latter part is opened, and some iodine being introduced, is again closed. The iodine vapor penetrates the capillary end, and changes the mercurial sublimate to iodide. According to Lehmann the sensitiveness of the test is heightened if this reaction takes place in a slow current of air while the gold electrode is cautiously heated, and the mercury volatilized in presence of iodine. In this way 0.1 milligramme of mercuric chloride may be detected in one hundred cubic centimetres of urine.

Mayer's method, by which the mercury is distilled in presence of steam, is even more sensitive. Urine or the finely divided organ diluted with water is mixed with slaked lime and solution of potassium hydrate in a flask having a capacity of about three times the volume introduced. A U tube filled with glass wool moistened with silver nitrate is connected with the flask, and both are heated in a calcium chloride bath to 130° C. or 140° C. The glass wool is afterwards inserted in a tube and the mercury converted into iodide. A two per cent. solution of sodium chloride may advantageously replace the water used in this method, frothing being avoided, and the mercury more rapidly volatilized. By this method 0.1 milligramme of mercuric chloride may be detected in one litre of urine.

After subcutaneous injection of mercuric chloride to the amount of three or four milligrammes daily for five days in a rabbit mercury was found in greatest amount in the heart, lungs, liver, and muscles, least in the brain, bones, and urine.

DESTRUCTION OF TISSUES.

P. Jeserich¹ recommends chloric acid in place of hydrochloric acid and potassium chlorate for the destruction of organic substances as a preliminary to their examination for inorganic poisons. The organic matter is finely divided and mixed with water to a thin paste, the chloric acid is then gradually added in small quantities, and the mixture carefully heated on a water bath. The mass swells up after a short time, and assumes a fungus-like appearance. If hydrochloric acid is then added in small quantities chlorine is set free, and acts rapidly upon the organic matters. Further treatment is similar to that employed in the ordinary process with hydrochloric acid and potassium chlorate.

Care must be taken that chloric acid is always in excess in order that lower oxidation products, which might be formed, shall not be volatilized, and also that concentration is not carried too far, otherwise the energetic action of the chloric acid upon the organic matter may give rise to slight explosions accompanied by flame.

By making use of chloric acid the presence of a large amount of potassium salt, which is introduced into the substance under examination when hydrochloric acid and potassium chlorate are employed, is avoided, and the liquid thus prepared may be tested for an excess of potassium salts in cases of poisoning with such substances as potassium oxalate.

Hospital Practice and Clinical Memoranda.

RHODE ISLAND HOSPITAL.

REPORTED BY DR. G. W. ALLEN, HOUSE SURGEON.

SURGICAL CASES. SERVICE OF DR. G. W. CARR.

OBSCURE ABDOMINAL TUMOR.

CASE I. T. McD., aged thirty-three, admitted to hospital November 28, 1882. Five weeks ago was caught between two freight cars and received injury to abdomen. He vomited a great deal at the time, and had severe pain in the region of the heart. Since then has been confined to his bed with pain and great weakness.

Physical examination shows hardness of abdomen just below the ribs on the left side. Pulsation of aorta quite distinctly transmitted to slight pressure.

December 9th. At times since admission he has had considerable pain, lancinating in character, in the cardiac region. Relieved by poultices. Has also begun to have fluctuations of temperature, which he did not have when he came in.

December 12th. Examination shows an oblong fluctuating tumor extending from the left hypochondrium to about two inches to the right of the umbilicus and nearly to the crest of the left ilium. Pulsation of aorta transmitted. Aspirated three inches to left of umbilicus and two inches above crest of ilium. Needle introduced about one fourth of an inch. Ninety-two and a half ounces thin, reddish-brown, odorless fluid drawn off, of specific gravity of 1020, containing albumen one half per cent., and red blood corpuscles; urea absent. Patient much relieved, but quite prostrated. Soon recovered, however. Compression applied.

December 13th. Feels very much better. Appetite improved.

December 17th. Has gained strength daily, and is up and about.

December 19th. Slight pain and fluctuation on left side. Rest in bed and compression ordered.

December 29th. The tumor has been gradually increasing, and is now as large and extends over the same area as when first aspirated. Aspirated again at same place. One hundred and seven ounces thin, dark-greenish, odorless fluid drawn off. Specific gravity of first part, 1014; of last part, 1010. Albumen one fourth per cent. Patient greatly relieved, and has little pain. Compression applied.

January 18, 1883. Has had no pain; has been improving steadily in general condition since the last tapping and now feels quite well. Dullness and fluctuation over a small surface about the umbilicus.

February 13th. Has continued improving. No increase in size of tumor. No fluctuation. Pulsation of aorta still transmitted. Discharged relieved.

Was seen about a month later and reported that he still felt well, although unable to do hard work.

NECROSIS OF FEMUR. SUPPURATIVE ARTHRITIS OF KNEE.

CASE II. Alice M., aged twenty-eight, admitted to hospital October 13, 1882. There is a sinus discharging pus on the inner side of the thigh, lower third,

which she says she has had for a year. Has a great deal of pain. Dead bone is felt with the probe.

October 25th. Another sinus has opened on the outside of the thigh.

October 29th. Bagging of pus in the calf. Edema of foot and leg.

October 30th. Incision and counter-opening made in the calf, and drainage tube inserted.

November 6th. Free discharge of pus, and hectic fever.

November 19th. Swelling and pain in knee.

November 26th. Incision made at sinus on inside of thigh, and femur found eroded to the knee.

December 12th. Profuse discharge of pus continues from thigh and calf. Consultation. Amputation advised and refused. Free incision made in thigh, and drainage tube inserted.

December 17th. Patient has diarrhoea and suffers more pain.

December 27th. Diarrhoea has continued uninterrupted in spite of active treatment. Patient has been steadily losing strength, and is in a very low condition. Suppuration is increasing. Boils have broken out on the back.

December 28th. Thigh amputated five inches above the knee. Anterior and posterior flaps, Lister. Knee-joint and lower part of femur found diseased. Temperature after operation 97.5° F.; pulse 160. Several hypodermic injections of brandy given. Brandy by mouth not retained. Brandy and beef tea, one ounce of each, given every hour by rectum, but not retained. Later, small doses of brandy and wine whey retained by the stomach. Evening temperature 102.2° F.; pulse 160.

December 29th. Temperature 102.6° F.; pulse 160. Is in a very feeble condition, and complains of great pain. During the last twenty-four hours has taken wine whey thirty-seven ounces, brandy fifteen ounces, beef tea eight ounces, and has had seven dejections. Tannin and opium suppository after each dejection. Drainage tube syringed through every three hours with solution of carbolic acid, one to forty.

December 30th. Temperature 103.8° F.; pulse 164. Stitches and drainage tube removed, and stump dressed loosely with carbolized gauze. Takes a large amount of wine whey and brandy. Has had four dejections.

December 31st. Temperature, morning, 103.2° F.; evening, 102° F.; pulse 164. Sleeps very little. Diarrhoea, nausea, and vomiting. Stump syringed every three hours with solution of carbolic acid, one to forty.

January 1, 1883. [The case passed this day into the service of Dr. E. T. CASWELL.] Temperature, morning, 103.6° F.; evening, 100.8° F.; pulse 160. Gradually growing weaker. Diarrhoea no better. Nausea and vomiting have ceased. Takes nourishment and stimulants well.

January 2d. Morning temperature 102.4° F., pulse 164; evening temperature 99.8° F., pulse 140. Mind wandering. Diarrhoea, nausea, and vomiting. Stump is suppurating and looks unhealthy.

For the next three days temperature averaged about 100° F., and pulse 150. General condition no better.

January 6th. Diarrhoea continues. Vomiting has ceased.

January 9th. Improving.

January 10th. Very delirious during the night. Diarrhoea as bad as ever. Nausea and vomiting again. Temperature 100° F.; pulse 140, and varied but little from this for the next two weeks.

January 11th. Still delirious. Had nine dejections, four involuntary. No nausea nor vomiting. Stump looks badly.

From this time, under a liberal allowance of stimulants, the patient very gradually but steadily improved. Diarrhoea, nausea, and vomiting had ceased by the 18th. The stump soon cleaned off and healed quite rapidly, except a sinus, which remained open until a small piece of dead bone was removed several weeks later.

COMPOUND FRACTURE OF FRONTAL BONE.

CASE III. Mary C., aged nineteen, admitted to hospital November 21, 1882, was injured by jumping from the window of a burning building. There was a lacerated wound about four inches long above the left eye, at the bottom of which could be felt a fracture of the bone with the outer table depressed. No symptoms of compression. Wound closed with adhesive plaster, and dressed with iced phenyl.

November 22d. Nausea and vomiting. Patient nourished by enemata. Delirious at times.

November 25th. Takes nourishment by the mouth and retains it. No nausea. No head symptoms.

December 5th. The scalp wound has healed by first intention. Complains of pain and tingling sensations in the left leg from the knee to the toes, and there is tenderness on pressure over the lumbar vertebrae.

December 14th. Discharged improved.

Some weeks later was perfectly well, no spinal symptoms having developed.

SERVICE OF DR. E. T. CASWELL.

FRACTURES OF THE FEMUR.

CASE I. G. R. C., aged twenty-one, admitted to hospital February 5, 1883, fell out of a window and fractured his femur at the middle third, shortening one and one fourth inches. Put up in Buck's extension with a weight of twelve pounds.

February 24th. Passive motion of knee.

March 9th. Plaster-of-Paris spica, extending to the knee, applied.

March 10th. On crutches.

March 12th. Union not very firm. Patient put to bed again.

March 19th. Spica removed and made into anterior and posterior splints. Good union and position. Splints applied, and patient up on crutches. Passive motion of knee every day.

March 28th. Discharged well. Shortening one fourth inch. To wear the splints two weeks.

CASE II. P. C., aged twenty-nine, admitted to hospital February 8, 1883, fell on the ice and fractured his right femur at the upper third. Shortening one inch. Put up on a double inclined plane with coaptation splints and extension with a weight of twelve pounds.

February 24th. Double inclined plane removed, and Buck's extension substituted. Passive motion of knee.

March 2d. Plaster-of-Paris spica, extending to the knee, applied.

March 5th. On crutches. Passive motion of knee every day.

March 16th. Goes up and down stairs on crutches.

March 22d. Spica made into a splint by removing the body band.

March 29th. Discharged well. Shortening imperceptible. To wear the splint two weeks.

CASE III. W. A. J., aged thirty-seven, admitted to

hospital February 8, 1883. The left femur was broken at the lower third by a falling tree. Injured leg slightly longer than the other. Patient says the right leg was always shorter than the left. Put up in Buck's extension with a weight of twelve pounds.

February 24th. Passive motion of knee.

March 7th. Plaster-of-Paris spica, extending to the knee, applied.

March 8th. On crutches. Passive motion of knee every day.

March 22d. Spica removed and made into a splint.

March 28th. Discharged well. Shortening imperceptible. To wear the splint two weeks.

CHRONIC SUPPURATIVE ARTHRITIS OF KNEE. AMPUTATION.

CASE IV. T. C., aged twenty-one, admitted to hospital March 9, 1883, with a history of trouble in the knee, of two years' standing, following an injury. Three weeks ago a sinus opened on the inside of the knee, through which the probe shows the head of the tibia and condyle of the femur to be eroded. Has considerable pain.

March 17th. Resection of joint advised on consultation.

March 20th. Resection having been performed, the disease was found to penetrate so far into the shafts of both tibia and femur that a shortening of five inches would be required to reach healthy tissue. Amputation was therefore decided upon, and this was done in the lower third of the thigh, a long anterior skin flap and a posterior muscular flap being made. Lister dressing.

The patient's condition improved greatly after the operation, and his appetite, which before had been very poor, began to improve immediately. He had very little surgical fever, and the wound healed quite rapidly with the exception of a sinus where the drainage tube had been, in which considerable pus collected.

COMPOUND FRACTURE OF TIBIA AND FIBULA.

CASE V. M. S., aged twenty-six, admitted to hospital March 17, 1883. Twelve weeks ago a log of wood fell upon his right leg, fracturing the tibia and fibula and inflicting an open, contused wound over the seat of fracture. It was put up on a double inclined plane with insufficient padding, and has not been touched until now. The calf is flattened out of shape by constant pressure, and there is a bed sore on the heel. Extensive necrosis of tibia found on probing through two large ulcerated openings over the fracture. No union of fragments. General condition very poor; patient is weak, thin, and pale.

March 22d. The patient has been kept on his side with his leg on a pillow, and it has now recovered its natural shape, although quite swollen and oedematous. Shortening two inches. Fenestrated plaster-of-Paris splint applied, the leg being extended as much as possible.

March 23d. Very comfortable. Sitting up. General condition has improved very much.

March 31st. On crutches. Up and about all day.

April 7th. Leg examined under ether. There is quite firm union of the fragments. Sequestrum not sufficiently loose to be removed. Bed sore has entirely healed.

April 22d. As far as general condition goes he is well and strong, and has gained flesh rapidly. The

dead bone is not yet quite loose enough to be removed. He continues to wear the splint. Discharged at his own request.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

CHARLES H. WILLIAMS, M. D., SECRETARY.

APRIL 16, 1883. DR. J. STEDMAN reported three cases of

POST-MORTEM DIAGNOSIS.

CASE I. Architect, age twenty-eight. Has never been very robust; while in college was thrown from a horse, but remounted and rode two miles without difficulty; had no unpleasant after effects. For the last year has had occasional severe headaches, and once called things by their wrong names.

March 3d he appeared well, worked during the day, and dined with a good appetite. At four o'clock the next morning had a severe attack of headache, for which he took thirty drops of laudanum; repeated in an hour. The headache increasing he was seen by the doctor, who gave four drachms of ether by inhalation, which quieted the patient, and gave natural sleep at eleven o'clock. When seen at half-past twelve he was found to be dead, but this had happened so quietly that those in the room did not know it.

The autopsy by Dr. Fitz showed cerebral substance anæmic and dry, lateral ventricles distended with a clear watery fluid, and one third larger than normal size. A gray gelatinous tumor the size of a filbert was found upon the velum interpositum in the median line behind the fifth ventricle in the region of the anterior commissure, on a level with the junction of the corpora striata and optic thalami. The tumor was easily removed from its surroundings, and on examination proved to be cystic, with gelatinous colloid contents.

Diagnosis. Colloid cyst, presumably of choroid plexus; ventricular dropsy.

In reply to Dr. Blake, DR. FITZ stated that there was nothing in the tumor to indicate its age, and that death took place probably from suffocation due to anæmia of the brain. The case is a rare one, although a similar case is reported in the early numbers of Virchow's *Archives*, where a soldier who was weak in mind and body was transferred to an invalid home; the symptoms increasing he was sent back to the hospital, and died. The autopsy showed a tumor of the same region with ventricular dropsy. In the case reported the absence of symptoms during life was probably due to the situation of the tumor.

CASE II. Woman, age about fifty years. Came from the Provinces to be under the care of a quack. He took a fee of \$200, and told her that she had a cancer which he could cure in four months.

Some months afterward, while visiting a friend, she was suddenly taken ill. The quack refused to see her unless she paid him a fee of \$300, but sent some medicine to be taken according to printed directions. When the patient was seen by Dr. Stedman she was moribund, and died within twenty-four hours.

The autopsy, by Dr. Ernst, showed left pleura adhesive throughout; heart soft and flabby; walls thinned; fatty infiltration of muscular tissue; in the left iliac

region extensive adhesions of the intestines to the pelvic wall. Microscopic examination of kidneys showed almost complete fatty degeneration of the convoluted tubules; both kidneys were enlarged, and had the cortical portion thickened and swollen.

Diagnosis. Chronic parenchymatous nephritis, and cardiac exhaustion.

CASE III. Woman, eighty-four years of age. Has been a widow sixteen years. Was always well until about three months after going to Europe, when she was taken sick, and was confined to her bed for a week. After this a painless diarrhoea set in, which continued some seven months, when, after a very painful journey from Florence to Bologna, she had a severe chill, followed by the breaking of an abscess in the vagina and the discharge of very offensive pus. She remained under the care of Dr. Benetti for five months, who writes that the patient had a pelvic cellulitis of the left iliac fossa which discharged large amounts of pus into the vagina; this gradually disappeared and the opening cicatrized. The patient was then attacked by intermittent fever, followed by a return of the diarrhoea, from which she made a slow convalescence. Some fourteen years later she had a return of intestinal disturbance and some bronchitis, of which she died.

The autopsy by Dr. Cutler showed old peritoneal thickening of the mesocolon, of the descending colon, and sigmoid flexure. Cicatricial thickening of the mesentery here and there. Old adhesions at the entrance of the ileum into the cæcum. Liver atrophied. The kidneys presented the characteristics of the senile granular change. There were old adhesions in Douglas's space between the fundus of the uterus and peritonæum. The left Fallopian tube was occluded near its extremity, and attached to the left ovary, which showed a cystic degeneration. In the posterior wall of the uterus was a fibro-myxoma about the size of an orange. Just below and to the left of the external os was a cicatrix in the vaginal wall leading up to the connective tissue of the left broad ligament, and to the subperitoneal tissue of the side of the pelvis. The rectum was contracted by cicatricial bands in the peritonæum. The lungs were emphysematous along their upper portions; in the left an atelectasis of the lower portion of the lower lobe, and a spot of recent pleurisy in posterior portion of upper lobe. The bronchi to their smallest divisions were injected. The mucous membrane thickened and covered with muco-purulent secretion.

In reply to Dr. Blake, DR. CUTLER said he had never seen a case where there was such an amount of cicatricial tissue in the abdomen. The rectum was so bound down that a finger could hardly be passed into it.

DR. STEDMAN said that for two years before death the patient required artificial aid for an evacuation of the bowels, and at one time there was an appearance of a tumor in the left iliac fossa, caused by some coils of intestine being caught by one of the cicatricial bands.

— A bust of Professor Erichsen and a sum of money were presented to him a few weeks ago by a number of his pupils and admirers. The bust is deposited in the University College. Mr. Erichsen will use the money to found a prize for skill in operative surgery.

Recent Literature.

Electricity in Medicine and Surgery. By GEORGE C. PITZER, M. D., Professor of the Theory and Practice of Medicine in the American Medical College, St. Louis, Clinical Lecturer at the City Hospital, St. Louis, Editor of the American Medical Journal, etc. Second edition. St. Louis, Mo. 1883.

The first edition seems to have been issued some time in January, 1883. The preface to this edition is dated May 1, 1883. It seems from the preface that the first edition was exhausted in a few weeks. Either the first edition was very small or there was a woful dearth of reasonably good books on electricity in that section of the country.

It has seldom been our fortune to notice a book so lacking in system or logical order, so worthless in regard to the object sought.

The first part, on machines, seems to be fairly well written, though we have not thought it worth while to read it. The portion devoted to electro-therapeutics is rather a hash. There is no attempt at systematic treatment. On pages 32 to 35 an attempt is made to explain the value of electricity in diagnosis, but electro-diagnosis is not mentioned otherwise until page 81; between these he briefly considers painful affections, as neuralgia, quoting four pages, central galvanization, electrolysis, the removal of hairs, quoting nearly twelve pages from Dr. George H. Fox, then various miscellaneous diseases, as of the skin, amaurosis, amenorrhœa, lead-poisoning, lumbago, rheumatism, local atrophy, etc. He then has a chapter on "the wrong current," quoting four pages. Liberal quotations are made in regard to detecting malingerers, detecting death, the use of electricity in asphyxia, and about static electricity. We have given above nearly the whole table of contents, to show how little order and how little value there is in the book.

As an example of the style of the original portion we should like to quote a whole page, but content ourselves with part of one page, omitting a few sentences. Speaking of facial paralysis he says, "This is not our first case, no, indeed, and from the experience and observation we have had we have learned to make successful and satisfactory examinations in this class of diseases. Well, how are we to know whether this is a case of central or peripheral disease? . . . But one of the most important and certain tests for central or peripheral paralysis is electricity, and I resorted to it. I have Kidder's electro-magnetic machine, and I tip the cup holding the fluid, attach the cords, upon the distal ends of which I attach sponge electrodes wet with warm water. I place the electrode. . . . I commence with a mild current; . . . I increase the strength. . . . I am pretty well satisfied. But I have a galvanic battery, . . . and I change the cords. . . . I now place the electrode, . . . and as I move it about over the cheek I observe a drawing of the face, . . . and as I move the sponge toward the temple the eye closes. All this convinces me that we have a case of simple peripheral paralysis." Why the change from first person singular to plural? Fourteen I's in one page is a fair allowance.

There are some useful hints in the book, but so much is omitted which ought to be included in even an elementary work of this nature that the book is of very little value.

Medical and Surgical Journal.

THURSDAY, AUGUST 9, 1883.

No. 4 PARK STREET, BOSTON, MASS.

EPIDEMIC CHOLERA.

ALTHOUGH cholera has been a common disease in India almost from time immemorial it is only since the great development of commerce and intercommunication between nations of the present century that it has prevailed outside of Asia. A little over sixty years ago the first European epidemic occurred, not extending farther west, however, than the Russian frontier. Since then the disease wholly disappeared from Europe less than one year in three, and it has been prevalent in a pestilential degree once in each decade, the second, third, fourth, fifth, and sixth epidemics extending to the westernmost parts of Europe, and reaching this country respectively in the years 1832, 1848-49, 1854, 1865-66, 1873, for the most part through the ports of Quebec, New York, and New Orleans. The last epidemic in this country was the most widespread of all, partly because the country had become so much larger. In 1865-66 the disease was shown to be, to a very great extent, controllable by sanitary inspection and control even in places where local conditions were favorable to its spread. In 1873 it was fatal in two hundred cities and towns of thirteen States, for the most part in or starting from the Mississippi valley.

So far as we can judge, therefore, the time is near at hand when another cholera epidemic may be reasonably expected, and there can be no doubt that it has already appeared in Egypt. No other disease than Asiatic cholera, with similar symptoms, would cause over three hundred deaths a day in a city of the size of Cairo.

The fact is established beyond a doubt that the "germ" of cholera is transportable in merchandise, in clothing, in bedding, and in the person of unclean people, often in ways the most difficult to trace. The source and method of its last introduction into the United States, for instance, have never been satisfactorily explained. It is equally true also that cholera never spreads to a dangerous extent when once imported except in nasty places. It does not prevail in all nasty places, nor in nasty places in proportion to their nastiness. In fact our last epidemic was very fatal in Nashville, where yellow fever, five years later, fell very lightly, while it was mild in Memphis and New Orleans, which were so scourged in our great yellow fever epidemic of 1878. Some of us have thought that many of our cities have tried to see how

far they could avoid the expense of cleanliness and yet keep clear of pestilences. Perhaps some of our neighbors think that a city which drinks the drainage of Woburn and Winchester and the sewage of Natick, and in whose chief source of water supply a legislative act allows promiscuous bathing, is trying to see how nasty it can be and escape disease.

The questions which interest us most in the prevention of cholera at this time are (1) whether cities can be cleaned to the extent of not fearing cholera if it is imported, and (2) whether the importation of the disease can be prevented.

To the first question the most striking affirmative answer is in Hamburg, which was very extensively destroyed by fire after the first cholera epidemic which reached western Europe, and was so cleaned and provided with good sewerage (the first city to be well sewered), and good and abundant water supply, that the succeeding cholera epidemics have been of little account there. After the second visitation of cholera in London, similar cleaning up, especially of the water supplies, was done with similar results. Such conspicuous examples were at once published abroad, so that the number of cities that have "cleaned out" cholera is now quite large. Many of our cities are still up to the standard of cholera-filth; how many are beyond it we do not know. It is certain that, in time of a threatened epidemic, it is seldom that there is time to complete sewerage works or radically improve water supplies.

As to preventing the importation of cholera, there is much to be said on both sides. It probably is not possible to be always successful in so doing, but the simple facts that in nine different years cholera has got so far as the New York quarantine station without being allowed to spread farther, and that in only seven years it has become widely prevalent, make it worth while to spare no effort to prevent a single case or a single infected article of clothing or merchandize, especially rags, which often go by most circuitous routes from one port to another, from being landed, without every precaution possible being taken to thoroughly isolate the sick person and to effectually disinfect the ship by destroying or fumigating, as the case may require, all infected or suspicious matter.

It is a matter of congratulation that our city Board of Health is just about to put up a building large enough to store and disinfect any dangerous matter that may come to our port. They have ample power under our laws, and may be safely trusted to exercise it wisely.

VITAL STATISTICS OF PROVIDENCE.

THE twenty-eighth Annual Report of the Births, Marriages, and Deaths in the City of Providence, has reached us, covering the year 1882. This report, made by the Superintendent of Health and City Registrar, Dr. Edwin M. Snow, always shows careful and laborious work, and contains much valuable statistical information. This city has now reached a population of nearly 117,000, so that it forms a tolerably good

representative of New England urban vital conditions. For this reason its statistics have a much more than local value and significance.

For the year 1882, as well as for the average of the last twenty-eight years, the number of births has been greater in December than in any other month. In interesting connection with this we may place the fact that last year, as for the previous years, the per cent. of marriages in the first quarter of the year has been lower than that in any other quarter except the third, while the fourth quarter of the year is always most prolific in marriages.

The male births show, as heretofore, a constant preponderance over the female. The average for the last twenty-nine years has been about 51.43 males and 48.57 females in 100 children.

Of the 2788 children born during the year about twenty-four per cent. were the first born of their mothers, and the 2759 mothers parturient during the year have had in all 9974 children, giving an average to each mother of 3.62 children.

The oldest mother in 1882 was 50 years of age and bore her third child in 1882. The number of mothers of 40 years and over, bearing children in 1882, was 128; the number of children borne by them during the year, 128; the total number of children borne by them, 927; an average of 7.24 children to each mother.

The number of plurality births during the year was 29, in all cases twins. In 11 cases both children were males; in 10, both were females; and in 8 cases there was one child of each sex; in all, 30 male and 28 female children. The proportion of cases of plurality births to the total labors was for the year 1 in 95. For the last twenty-eight years, 1 in 85.

We fail to find in this report any figures showing the number of divorces, a subject which we have found of interest in the previous annual reports.

The total deaths for the year were 2242, the rate being 19.60 per 1000, which is about the average.

The average age of decedents of American parentage, was 33.72 years, or 0.44 year less than in 1881; of decedents of foreign parentage, the average age in 1882, was 30.34 years, which was 2.26 years more than in 1881, and was the highest average age ever recorded for decedents of foreign parentage.

It is noteworthy that with the exception of two months in 1882 every month for twenty-eight years has shown a greater average longevity of American decedents than of those of the foreign class, the average difference between the two classes for that period having been 8.93 years.

An interesting table is given showing in detail the causes of death, and their prevalence in each month of the year. The predominance of diarrhoeal diseases in the summer months is, of course, marked, as is also that of diseases of the respiratory organs in the first and last quarters of the year. Among the other causes of death we notice childbirth, 27 cases (of which puerperal fever constituted 18). These 27 deaths were 1.21 of all deaths from known causes, and 0.98 per cent. of the mothers having children during the year.

Consumption caused 15.72 per cent. of the total deaths, and the ratio of deaths from this disease to the whole population was 3.07 in a thousand. The most important disease of the year, from a hygienic point of view, was typhoid fever, which caused 140 deaths, against a greatest previous maximum of 82 in any one year, the average of twenty-eight years being only 42. The disease became fairly epidemic in October and November. On this point the report says:—

"There were no special indications of the fever in 1882 up to the last of October. There were only 42 deaths in all the year to the 1st of November; there were 9 in September, and only 8 in October. In fact, at the middle of the month of October there seemed to be less typhoid fever in the city than was usual at that season. Only 13 cases were then or afterwards reported as having commenced from the 1st to the 20th of October inclusive.

"After the 20th of October the number of cases increased rapidly, and the disease speedily became epidemic. During the ten days, including the last five days of October and the first five days of November, 212 cases were reported, the greatest daily number being 45, on the first day of November. From that date the disease declined slowly in November, much more rapidly in December, and almost entirely disappeared in January, 1883.

"It seems, then, that the epidemic reached its height in ten or twelve days after its beginning, and that after a certain date (October 20th), at which there was scarcely any typhoid fever in the city, within fifteen days 248 cases were reported. These cases were in almost every portion of the city, and without any apparent tendency to concentration in any particular locality. This fact seems important with reference to the popular theory that there must be a direct connection of every case of typhoid fever with some preceding case.

"Though the disease had almost disappeared in January and February, 1883, another epidemic of less severity and extent began about the 16th of March. There were 61 cases reported in the twelve days from March 16th to March 27th inclusive. After the latter date the disease rapidly declined."

The registrar promises fuller details of the history, and more especially of the causes of the disease, to be given hereafter in a special report upon the epidemic.

It is to be wished in the interest of social science that other municipalities would publish as elaborate and reliable reports of their vital statistics as does the city of Providence.

MEDICAL NOTES.

— According to a telegraphic dispatch to the *Boston Journal*, a pastoral of Mgr. Fabre on the Laval University and Victoria College question was read in all the Catholic churches in Montreal on Sunday last. The pastoral commands the Sister Superior of the Hotel Dieu not to admit the Faculty and the students of Victoria College within the precincts of the hospital hereafter, and to allow the Medical Faculty and stu-

dents of Laval University to take their places. It excommunicates the Faculty of Victoria College, and urges the priests to deter the youth of their flocks from patronizing that Protestant seat of learning under pain of excommunication should they transgress the Pope's mandate on that subject.

— A member of the class of 1883 of the College of Physicians and Surgeons of Baltimore, who was rejected in his candidacy for a diploma, petitioned the court to issue a writ of mandamus upon the Faculty that they shall issue his diploma to him, claiming that his rejection had damaged his character to the amount of \$2000. After argument before the court the judge decided in favor of the Faculty. An appeal has been taken.

— Dr. Louvain, of Carlsbad, has met with several cases in which difficulty of breathing was due to the administration of moderate doses of salicylic acid; the breathing was labored and rapid. — *Berl. Klinische Wochenschr.*, 1883, No. 16.

— In the shipwreck of the Portuguese barque Pimpao, on the coast of Pico, June 28th, among the lost was Dr. Edward Mead, of Roxbury, who was taking a voyage to the Azores for recreation and health. Dr. Mead was born in England in 1819, coming to America in 1832. He early made medicine his study, graduating from the Medical College of Ohio in 1841. He made insanity his specialty, and was a very devoted laborer in his profession. From 1842 to 1852 he successfully conducted a private asylum at Chicago, removing in the latter year to Cincinnati, where he resided from 1852 to 1869. At Cincinnati he filled several public positions, and during the war was an active member of the Sanitary Commission. Since 1870 he has been in Boston, where he established a private institution in 1872. He held at one time a professorship in the Medical Department of Illinois College, and later a similar position in the Cincinnati College of Medicine and Surgery. At the time of his death he was a member of the Massachusetts State Medical Society, and was one of the councillors of the Norfolk District Medical Society. Dr. Mead leaves a widow and one son in Boston, and two daughters and a son at the West.

— M. Pasteur having offered to organize a mission for investigating the cholera in Egypt, the Hygiene Commission has indorsed the scheme. The mission will consist of M. Roux and M. Thuillier, of M. Pasteur's laboratory; M. Strauss, of the Faculty of Medicine; and M. Nolaco. M. Pasteur has written to Lord Granville to solicit the grant of facilities to the mission in Egypt.

— The *Lancet* says in answer to a correspondent: It is probable that the best American degrees will be registrable under the new act. Two conditions will be indispensable—the first, that the degree shall qualify for practice in the country in which it is granted; the second, that the Medical Council shall be satisfied that it represents an amount of education equal to that required for passing the examination of the new Board to be established.

— A writer in the *Maryland Medical Journal* describes the Juries of Matrons formerly employed in that

State on writs *de ventre inspiciendo*, in cases of suspected pregnancy. Cases are given of indictments for child murder, adultery, etc., as well as where women were under capital sentence, where these juries of "twelve respectable women, assisted by the sheriff," examined the prisoner and reported on the existence or non-existence of pregnancy. The custom seems to have come from the English common law, and though not used since 1769 has never been formally abrogated in the courts of Maryland.

— The *Sanitary Engineer* tells a recent story from Texas, which illustrates in a grotesquely horrible way the indifference of people to the condition of their drinking-water. A public well in Brownsville was cleaned out a short time ago, and in it were found the remains of a prisoner who had disappeared, it is said, several years since. Then the people remembered that, to be sure, the water did at one time taste bad, and hair and flesh had been found in it. But as it was supposed these came only from drowned rats or cats, they went on drinking the water unconcernedly. The question of dirt was of no importance; distilled dead animals they endured with equanimity—only when it proved to be dead prisoner did they attach any importance to the bad taste and smell.

— A coroner's jury in a Pennsylvania town has found a physician guilty of criminal ignorance in prescribing a drug (acetate of potassium) in a case where death resulted by reason of the drug actually dispensed having been cyanide of potassium, the bottle actually containing the latter substance having been wrongly labeled. A similar accident had occurred once before, but without fatal result, the patient having refused to take more than one dose. On receiving another prescription soon after for the same drug the clerk (who was merely a salesman in an ordinary "country store," and who knew nothing of pharmacy) told the physician how the medicine had affected the former patient. The doctor asked to see the jar containing the acetate, and after examining it he said: "Clark may have had a fit, but this medicine never caused it; it is all right; weigh out an ounce for Mr. Swift." He then gave Mr. Swift the package, and gave him verbal directions how he should use it. The first dose proved fatal. It is stated that after the death of the patient Dr. Gray examined the medicine once more in the stock bottle at the grocery, tasted it, rubbed a little between his thumb and finger, said it felt "greasy," but still called it acetate of potassium, and said he thought the medicine had nothing to do with the patient's death; thought he died from congestion of the brain. The evidence of the autopsy, however, was otherwise. It is to be hoped that the jury which has justly held the physician to so strict a responsibility for not recognizing the physical appearances of a wrongly labeled drug after his attention had been called to the likelihood of a mistake as to its nature, will be equally severe in punishing the carelessness which permits a seller of country "notions" to dispense a deadly drug of whose nature he is totally ignorant.

— *Science* reproduces from Pflüger's *Archiv* the

following on the heart as a suction-pump: It has long been discussed whether the ventricle of the heart is not only a force-pump in systole, but also a suction-pump in diastole, actively dilating, and drawing blood into it from the veins. That within the closed thorax there is, due to the negative pressure prevailing in that cavity, an active diastole cannot be doubted; but is there such a diastole when the chest is opened, or does then the blood returned to the heart from the veins merely push apart the flaccid walls of the heart-chambers?

Goltz and Gaule have, among others, maintained the doctrine of such active diastole. Even with an open thorax, they found a negative pressure occurred in the heart during some part of a cardiac period; and, though their method of work did not enable them to determine at what moment in the heart's cycle this negative pressure occurred, they assumed that it was during the diastole. Moens, however, in a subsequent noteworthy paper, brought forward experimental and other proofs that the negative pressure in the left ventricle existed at the end of the systole, and not in the diastole at all; if so, the heart was not a suction-pump. Jager now returns to the question; and taking as starting-points the assumptions, that, if negative ventricular pressure occurred at the close of the systole it must show itself in the aorta, but if during diastole in the auricles, he concludes that it is diastolic; since his experiments show that at no time is there a negative pressure in the aorta, while there may be such in either auricle. Accordingly, he maintains that the heart is a suction-pump. We may remark, however, that the correctness of his primary assumption is by no means certain: hence his whole argument falls to pieces. There is, on the contrary, strong reason to believe that the ventricular contraction lasts after closure of the semi-lunar valves, and that it is just at this very end of the systole that the negative intra-cardiac pressure occurs.

— In Bellevue Hospital yard is a photograph gallery, where the hospital photographer takes photographs of all the unknown dead who are brought to the morgue. He places the coffin containing the dead body in an upright position in an angle of the morgue building, and makes a photograph of the face.

— The autopsies of some of the criminals executed in the early part of this century are published in an English contemporary, showing that instantaneous death by dislocation of the vertebræ was then rarely the case. That desirable result is claimed to have occurred in every one but one of "Marwood's" many executions, "Marwood's Drops" being now in jail slang the reliable sedative for all fleshly ills. But before this science had been so perfected, the careful autopsies showed some unpleasant facts. For instance, John Bellingham was executed in 1812. There was no dislocation of the vertebræ, according to the record, "nor did the trachea show any sign of compression or hurt. The right Auricle of the Heart moved at irregular Intervals, without the Application of any Stimulus, during the Period of nearly four Hours from the Time of Execution, and for about an Hour longer upon

being Touched with a Scalpel. This Motion was not strictly a contractile Action, diminishing in any sensible Degree the Cavity of the Auricle, it was undulatory and weak, sometimes beginning at the right extremity of the Auricle and moving to the left; at other times commencing and proceeding in the contrary Direction. Not the least Motion was observable in the left Auricle, or in either of the Ventracles." In the case of John Bruce, executed at Execution Dock at eight o'clock, and received so late as half-past twelve, there were the same weak waving motions for a period of *five hours after execution*.

— "An octogenarian," writing to an English contemporary, makes certain very suggestive reflections on the influence of vaccination on the people whom it protects. After expressing a wish that those who question the utility of vaccination could, without losing the advantages of youth, receive the memories of his own earlier days, he continues: "I may safely say that for every person I now meet with seamed or pitted face I then met a hundred, many grievously disfigured, and not a few blind. This was bad enough, though even then, thanks to small-pox inoculation, and more lately to the vaccine protection, sufferers were at least in a very decided minority; but I have heard my mother say that in her early days marks of small-pox were so prevalent that it was common to distinguish one free from them as a smooth-faced person."

NEW YORK.

— Another of the Alexandre line of steamers (the City of Merida) on which yellow fever broke out during the homeward voyage arrived in port on the 1st of August. She left Vera Cruz on the 19th of July, and before reaching Havana, on the 25th, eight of her crew were attacked with it. One of the engineers of the ship died from the fever, and the other serious cases were sent to the hospital in Havana. During the voyage from Havana to New York, however, there was no sickness on board.

— The first case of yellow fever to reach the port during the present summer arrived on the 31st of July on the bark Havana, from Havana. One of the crew was found to be suffering from the disease, and he was sent to the West Bank Hospital, while the vessel was put into close quarantine at the Hospital Islands.

— Notwithstanding the high mortality during the early part of the month, the number of deaths in the city during July was 374 less than in July of last year. The total number of deaths from January 1st to August 1, 1883, has been 3096 less than during the corresponding period of 1882.

— The steamship Glenarvon arrived from Yokohama, by way of the Suez Canal, on the 30th of July, and although she had stopped at no cholera port, and her captain reported that there had been no sickness on board during the voyage, she was ordered to lower quarantine, where she was subjected to a very thorough inspection. This having proved satisfactory, she was allowed to come up to the city. Health Officer Smith has made a regulation to the effect that the

shippers of rags from European ports shall make affidavits before the American consuls that the rags are "domestic," and not reshipments. If they are of the latter description it must be stated from what port they originally came. By following this regulation the shippers of cargoes of rags can prevent their needless detention at quarantine.

Miscellany.

THE MARRIAGE OF NEUROTIC PATIENTS.

In the *Journal of Mental Science*, April, 1883, is a paper by Dr. G. H. Savage on the vexed question of the propriety of marriage in individuals who suffer from insanity, epilepsy, or grave hysteria. After stating the opposite opinions that have been held on this point the writer says, "I am inclined to think that if it were possible for us to select those who are to be married, and if we selected only those who are nervously stable for the parents of the next generation, the children might suffer from a want of adaptability. They might, in fact, develop from nervous stability into nervous rigidity." In other words, it is possible for people to be too robust in their muscular and circulatory systems in proportion to their nervous development. In fact the most robust offspring are often seen from parents of which one is of a highly nervous temperament.

Regarding the effect of marriage upon the course of major hysteria, Dr. Savage says: "It would be harmful, in my experience, if every young hysteric were then and there married. The relief, if any, would be temporary, and the result to the developing organism would be disastrous. I do not myself believe that hysteria is generally benefited by marriage. I admit I have seen one case in which anorexia nervosa and extreme depression in a young, single girl passed off after marriage and the birth of children. On the other hand I have seen several cases in which the hysterical girl has become the insane mother, and the hoped-for cure by marriage has proved a delusive dream."

Next, as regards epilepsy, Dr. Savage writes: "I should dread the effects of marriage upon an epileptic almost more than those who had been insane. The comparative rarity with which epileptics get well and the mysterious causation of the whole epileptic condition make it a dangerous experiment to recommend marriage for the relief of these unknown conditions."

Individuals suffering from a complication of hysteria with insanity are believed to subject their children to a greater risk than those who have hysteria combined with mental disorder. Those who have been simply insane are not necessarily to be dissuaded from marrying. If the other party is of good health and free from nervous disposition a person who has had an attack of insanity may be allowed to marry provided he has not a markedly nervous inheritance.

"Another point is when a patient may be married, that is, how soon after an attack of insanity. Most of us have seen cases in which the insane inheritance has been transmitted directly, and, if I may say so, immediately. I have seen three or four cases in which children have been begotten by insane parents who were suffering from acute insanity at the time of their begetting. Such persons are almost sure to be weak minded, idiotic, or imbecile from birth. On the other

hand the greater the distance there is between the attack and the begetting of the child the less danger is there to the offspring. I am in the habit of saying that a general paralytic father rarely begets an insane child unless that child is begotten during the active stage of the disease. . . . A parent who has been insane may beget an insane child soon after recovery, before the attack, or during the attack of insanity, but may beget perfectly sane children in the interval."

In connection with the foregoing it is of interest to cite some rather surprising facts given by Dr. Bannister in the *New York Journal of Nervous and Mental Disease* (January, 1883), on the relative frequency of intermarriages of the insane. Of 104 cases of hereditary insanity recorded in the Illinois State Asylum no less than four had both father and mother insane; three others had it by direct paternal and collateral maternal heredity; two had direct maternal and collateral paternal heredity; and in one case there was collateral heredity of insanity on both sides. Thus nearly ten per cent. of those with insane heredity had it on both sides, and hence were favored with a double opportunity to inherit mental disease. If to these be added the instances where, with insanity in one parent, there is reported either epilepsy, hysteria, drunkenness, "brain disease," "nervousness," etc., of the other, the ratio of double inheritance rises to over twenty per cent. Three instances occurred in one asylum of husband and wife being patients together.

Perhaps, as has been suggested, this intermarrying of insane persons is due in part to the fact that cases of mental unsoundness become generally known to the public, and that as the sane hesitate to ally themselves with those who have been insane, so if the latter wish to marry they cannot easily obtain mates except among those who are similarly marked. Certainly if this be so physicians cannot be too sedulous in correcting the impression that insane people are only fit to marry each other.

PROLONGED SUSPENSION OF VITALITY DUE TO ATROPIA INJECTED HYPODERMICALLY.

DR. ALEXANDER, in the *Medical Times and Gazette* (May, 1883), reports a case of a woman, aged thirty-seven, who had been operated on for an enlargement of the left ovary. At noon, four days after the operation, she became very excited, and disturbed the dressings of the wound, so twelve minims of the hospital solution of morphia and atropine were injected. This represented three fifths grain of morphia and one fortieth grain of atropine. At one o'clock she became livid, and a nurse injected another five minims of solution before the house-surgeon arrived. When he came he injected ammonia, gave brandy enemata, used artificial respiration, and applied electricity without effect. At four P. M. the nurse was laying the woman out, but Dr. Alexander came in and determined to proceed with artificial respiration, galvanism, frictions. Up to 5.30 P. M. only a spasmodic breath every quarter of an hour and a feeble beat of the pulse every now and then could be detected. At seven P. M. a nurse poured some coffee into the patient's mouth, and she suddenly fell back as if dead, but by turning her over on her side she was made to vomit. By nine o'clock the respirations were beginning to be more frequent and the pulse stronger; she soon became conscious after this, and recovered perfectly.

REPORTED MORTALITY FOR THE WEEK ENDING JULY 21, 1883.

Deaths reported 3623 (no report from District of Columbia) : under five years of age, 2018 : principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 1454, diarrhoeal diseases 1142, consumption 358, lung diseases 128, diphtheria and croup 67, scarlet fever 52, typhoid fever 44, malarial fevers 39, measles 35, small-pox 27, whooping-cough 19, cerebro-spinal meningitis 16, puerperal fever seven, erysipelas six. From *typhoid fever*, Philadelphia 10, New York eight, Providence five, Brooklyn and Cincinnati three each, Boston, St. Louis, Baltimore, and Pittsburg two each, Chicago, New Orleans, Buffalo, New Haven, Charleston, Nashville, and Chelsea one each. From *malarial fevers*, New York and New Orleans 12 each, St. Louis four, Brooklyn, New Haven, and Charleston two each, Philadelphia, Chicago, Baltimore, Providence, and Nashville one each. From *measles*, New York 16, Baltimore five, Philadelphia three, Brooklyn, Chicago, St. Louis, Cincinnati, New Orleans, Pittsburg, Buffalo, Worcester, Chelsea, Newburyport, and Northampton one each. From *puerperal fever*, Chicago and St. Louis two each, Cincinnati, New Orleans, and Fall River one each. From *small-pox*, New Orleans 23, St. Louis three, Philadelphia one. From *whooping-cough*, New York nine, Philadelphia three, Brooklyn two, Chicago, St. Louis, Buffalo, Milwaukee, and New Haven one each. From *cerebro-spinal meningitis*, New York six, Chicago and Milwaukee two each, St. Louis, Baltimore, Pittsburg, Worcester, Brockton, and Peabody one each. From *erysipelas*, New York and Boston two each, Philadelphia and Cincinnati one each.

Three cases of small-pox were reported in St. Louis, Buffalo two; measles 23, scarlet fever 19, typhoid fever 12, and diphtheria 11 in Boston; scarlet fever 20, and diphtheria 10 in Milwaukee.

In 37 cities and towns of Massachusetts, with an estimated population of 1,129,159 (estimated population of the State

1,922,530), the total death-rate for the week was 22.22 against 27.01 and 20.04, for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending July 7th, the death-rate was 19.3. Deaths reported 3185 : acute diseases of the respiratory organs (London) 179, diarrhoeal diseases 249, measles 116, scarlet fever 71, whooping-cough 62, fever 39, diphtheria 19, small-pox (Birmingham three, London and Hull one each) five. The death-rates ranged from 10.8 in Brighton to 23.2 in Liverpool; Bristol 14; Leicester 15.3; Sunderland 16.4; Nottingham 17.3; Birkenhead 17.6; Manchester 19.1; Sheffield 19.4; Birmingham 19.5; London 20.1; Leeds 22.2. In Edinburgh 16.1; Glasgow 28.1; Dublin —.

For the week ending June 30th, in 169 German cities and towns, with an estimated population of 8,580,059, the death-rate was 28.9. Deaths reported 4764; under five years of age, 2619; consumption 585, lung diseases 432, diarrhoeal diseases 386, diphtheria and croup 137, measles and röteln 125, scarlet fever 82, typhoid fever 67, whooping-cough 43, puerperal fever 18, small-pox (Heilbronn eight, Breslau and Bremen two each) 12, typhus fever (Thorn one) one. The death-rates ranged from 16.4 in Mannheim to 44 in Berlin; Königsberg 29.7; Breslau 31.9; Munich 36.2; Dresden 26.7; Leipzig 23; Hamburg 26.5; Cologne 33.9; Frankfurt a. M. 28.4; Strasburg 21.5.

For the week ending July 7th, in the Swiss towns, there were 28 deaths from consumption, diarrhoeal diseases 21, lung diseases 20, diphtheria and croup five, measles four, whooping-cough two, typhoid fever two, scarlet fever one, puerperal fever one. The death-rates were at Geneva 18.4, Zurich 14, Basle 23.2, Berne 23.7.

The meteorological record for the week ending July 21st in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps : —

Deaths reported 3151 (no reports from Brooklyn, New Orleans, and District of Columbia): under five years of age, 1785: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 1305, diarrhoeal diseases 1019, consumption 317, lung diseases 123, diphtheria and croup 95, typhoid fever 49, measles 34, scarlet fever 32, malarial fevers 28, whooping-cough 23, puerperal fever seven, erysipelas three. From *measles*, New

York 21, Baltimore seven, Somerville two, Chicago, St. Louis, Charleston, and Nashville one each. From *scarlet fever*, Philadelphia nine, New York eight, Chicago five, Boston and St. Louis two each, Baltimore, Pittsburg, Buffalo, Milwaukee, Worcester, and Plymouth one each. From *malarial fevers*, New York 17, St. Louis six, Baltimore two, New Haven, and Springfield one each. From *whooping-cough*, New York 11, Philadelphia and Chicago three each, Baltimore two, St. Louis,

¹ Sixty-three deaths by drowning, twelve miles from the city, not included.

New Haven, Nashville, and Newburyport one each. From *cerebro-spinal meningitis*, New York five, Philadelphia, Chicago, Cincinnati, Pittsburgh, Nashville, Fall River, Lawrence, Holyoke, and Waltham one each. From *puerperal fever*, Boston four, St. Louis two, Chicago one. From *erysipelas*, Philadelphia, Cincinnati, and Providence one each. From *small-pox*, Philadelphia, one.

Fifteen cases of small-pox were reported from St. Louis; typhoid fever 17, scarlet fever 16, diphtheria 14, and measles 10 in Boston.

In 39 cities and towns of Massachusetts, with an estimated population of 1,180,189 (estimated population of the State 1,922,530), the total death-rate for the week was 28.43 against 22.22 and 27.01, for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending July 14th, the death-rate was 22.2. Deaths reported 3660: diarrhoea 452, acute diseases of the respiratory organs (London) 195, measles 119, scarlet fever 79, whooping-cough 60, fever 55, diphtheria 30, small-pox (Newcastle one) one. The death-rates ranged from 9.8 in Cardiff to 96.9¹ in Sunderland; Birkenhead 13.5; Bradford 15.3; Leicester 16.1; Bristol 16.9; Leeds 17.5; Brighton 18.3; Birmingham 19.5; Sheffield 20; London

22.9; Liverpool 23.3; Manchester 25.8. In Edinburgh 13.9; Glasgow 23.7; Dublin 20.6.

For the week ending July 7th, in 000 German cities and towns, with an estimated population of 8,589,892, the death-rate was 38.8. Deaths reported 6406; under five years of age, 4058; diarrhoeal diseases 684, consumption 604, lung diseases 430, measles and röteln 160, diphtheria and croup 146, scarlet fever 86, whooping-cough 64, typhoid fever 45, puerperal fever 13, small-pox (Heilbronn two, Breslau and Bremen one each) four. The death-rates ranged from 19 in Karlsruhe to 67 in Berlin; Königsberg 31.1; Breslau 45.8; Munich 33.8; Dresden 34.9; Leipzig 35.7; Hamburg 38.5; Cologne 44.4; Frankfurt a. M. 29.8; Metz 30.2.

For the week ending July 14th, in the Swiss towns, there were 38 deaths from consumption, diarrhoeal diseases 18, lung diseases 17, whooping-cough five, typhoid fever four, measles three, diphtheria and croup three, small-pox one, scarlet fever one, puerperal fever one. The death-rates were at Geneva 13.3, Zurich 8, Basle 16.7, Berne 20.3.

The meteorological record for the week ending July 28th in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

¹ This high rate is due to the registration of 177 deaths of children, resulting from the disaster at the Victoria Theatre, Sunderland.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM JULY 27, 1883, TO AUGUST 3, 1883.

TURRILL, H. S., major and assistant surgeon. Granted leave of absence for one month, to commence September 1, 1883. S. O. 77, Department of the Platte, July 26, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING AUGUST 4, 1883.

COLES, J. W., surgeon, ordered to the Naval Hospital, Philadelphia, Pa.

MARSTELLER, E. H., passed assistant surgeon, detached from the U. S. S. Hartford, and granted sick leave.

BRANSFORD, J. F., passed assistant surgeon, detached from the Naval Academy and ordered to the Hartford.

BOGERT, E. S., medical inspector, and FERREER, N. MCP., passed assistant surgeon, detached from the Navy Yard, Norfolk, Va., on August 30th, and ordered to the U. S. S. Trenton September 1st.

GATEWOOD, J. D., passed assistant surgeon, ordered to the U. S. S. Trenton September 1st.

KIDDER, B. H., surgeon, detached from the Naval Station, Port Royal, S. C., and ordered to the Navy Yard, Norfolk, August 30th.

APPOINTMENTS. BOSTON CITY HOSPITAL.—Dr. T. A. DeBlois has been appointed Assistant Physician to the Out-Patient Department for Diseases of the Throat.

Dr. F. H. Williams, Physician to the Medical Out-Patient Department.

BOOKS AND PAMPHLETS RECEIVED.—Treatment of Diseases of Infancy and Childhood, with over 400 Formule and Prescriptions, as exemplified in the Services of Drs. A. Jacobi, J. Lewis Smith, etc., etc. By Charles H. Goodwin, M. D. New York: Charles H. Goodwin. 1883.

A CONTRIBUTION TO THE TREATMENT OF
EMPHYEMA.¹

BY A. T. CADOT, M. D.

BEFORE proceeding to the consideration of the cases upon which this paper is based I wish to review briefly the mechanical principles involved in the expansion of a lung which has been compressed by fluid in the chest, and to show how this expansion may be favored by an appropriate dressing after the establishment of a free opening into the pleural cavity.

Suppose a case of empyema in which an opening has been made and the pus allowed to escape. Upon the removal of the pressure the lung at once expands somewhat by virtue of its own resiliency, and by the partial reestablishment of its circulation. Further, each contraction of the chest with closed glottis (cough or sneeze) presses the air from the well side over into the affected lung, partially expands this, and so forces the air or fluid in the pleural cavity out through the opening in the side. When the cough subsides, and the chest again expands, air rushes back to take the place of that just expelled. There are two avenues by which this returning air enters the chest; namely, the bronchus of the lung, and the opening into the pleural cavity.

If this latter opening be as free and unobstructed as the bronchus, the air has as ready access to the pleural cavity as to the bronchial tubes, and the pressure on the outside and inside of the lung being thus equalized it resumes its condition of semi-collapse.

If, however, the opening in the side is narrowed by the closing in of granulations or by the obstruction of a dressing, the air returning after a forced expulsion is somewhat opposed in its entry into the pleural cavity, while the bronchus admits it freely, so that the atmospheric pressure inside the lung is somewhat greater than upon its outer surface, and the dilatation effected by the cough is more or less maintained. It is thus that nature, with its fistulous openings, provides for the expansion of the lung, and we here, too, find the explanation of the gradual dilatation effected by the usual dressings of oakum or other absorbent material.

This gradual dilatation of the lung is liable to be interfered with by a provision of nature which here may act detrimentally to the healing process. I refer to the adhesion of the inflamed pleural surfaces when brought in contact. Of course, if the surface of a lung only partially dilated becomes firmly adherent to the parietal pleura, the further dilatation is greatly interfered with, and may become impossible. It is, therefore, very important to induce the lung to dilate to its fullest extent as soon as possible, so that the pleural adhesion, when it takes place, may bind things in their proper places.

That this rapid dilatation may be powerfully assisted by a proper dressing I shall endeavor to show.

The problem is to provide for the easy escape of air and fluids from the chest, and to obstruct the reentry of air into it.

A Lister dressing properly applied fulfils the required conditions more thoroughly than any other which I have seen in use. The method of application which I have found best is as follows:—

The tubes, of which I generally use two, side by side, are arranged so that they barely project within the chest wall, and the outer ends, after being securely fastened with safety pins and adhesive plaster, are cut off as close to the skin as possible. A handful of loose gauze wrung out in an antiseptic solution is placed around and over them, and over this a piece of mackintosh large enough to project in every direction beyond the gauze beneath it. Over this again are placed many (twelve to fifteen) layers of dry gauze, and lastly a sheet of cotton batting to provide for equal pressure. This whole dressing is held in place by a gauze or flannel bandage, some of the turns of which should go over the shoulder to prevent its slipping down.

The loose gauze next the tube catches and holds the discharge, which in a favorable case is reduced to almost nothing after the third or fourth dressing, and soon becomes serous.

This rapid diminution of the discharge under antiseptic treatment, and the fact that it speedily becomes serous in character, was pointed out some years since by Professor Lister; but he did not mention, and I have never seen elsewhere described, the great advantage of this form of dressing in favoring the expansion of the lung and obliteration of the cavity. This latter action of the dressing, which will, I think, be sufficiently manifest in the cases I shall report, is due to the method in which the mackintosh is applied.

This rubber layer, impervious to air, overlaps the gauze beneath it so that its edges are held closely applied to the skin by the elastic pressure outside. How closely it clings to the skin can only be appreciated by one who has frequently removed these dressings.

When, now, air is forcibly driven out of the chest by a cough, it lifts the edge of the mackintosh somewhat and escapes, but as the elastic outside dressings immediately press the mackintosh again to the side, the air which could lift it from within cannot get beneath it from without. It acts, in short, as a valve, allowing air to escape from under it, but not to get back again.

Dr. A. M. Phelps, of Chateaugay, N. Y., in an article in the *New York Medical Record* for April, 1880, upon The Treatment of Empyema by Valvular Drainage, recommends the use of a drainage tube with a valve attached which should allow the escape of fluids from the chest and prevent the entry of air. This contrivance I have never used, as I had already found that the antiseptic dressing accomplished this same object, with the additional advantage of guarding against septic absorption. I have, however, seen a valvular tube used by Dr. M. H. Richardson, who combined it with an antiseptic dressing, but did not find that it added to the efficiency of the dressing.

The following cases will illustrate the advantages of the antiseptic dressing, applied as I have described, both in preventing septic absorption and in promoting the expansion of the lung. They include all the cases of empyema which I have treated in this way, and one case (No. 3) which I saw with Dr. J. B. Swift, who operated antiseptically, and dressed the patient in the way I have described. All of these patients were operated upon under ether except where it is otherwise stated. The final removal of the tube in each case is emphasized as giving the date when the pleural cavity was finally closed. In none of them was there any reaccumulation or further discharge, and the opening always closed rapidly.

¹ Read before the Section for Clinical Medicine, Suffolk District Medical Society.

No.	Sex.	Age.	Medical Attendants.	Previous Duration of Disease.	Side Affected.	Previous Treatment.	Date of Operation.	Progress.	Result.	Remarks.
1	F.	11		1 month.	Right.	Aspirated once.	March, 1879.	Lung fully dilated three days after operation.	Tube removed on seventeenth day.	The lung was fully restored, and child recovered perfect health.
2	M.	29	Dr. R. Amory. Dr. F. I. Knight.	Uncertain.	Right.	Aspirated once. Fetid pus.	January, 1880.	Chill after operation. Normal temperature after second day. Attended business after ninth day.	Tube removed on twenty-eighth day.	Quickly recovered full health.
3	M.	1½	Dr. J. B. Swift.	2 months.	Left. Apex beat, below right nipple.	- -	February, 1880.	Lung dilated rapidly.	Tube removed on thirteenth day.	Operation without ether. Perfect recovery.
4	M.	33	Dr. J. L. Sullivan. Dr. F. I. Knight.	3 months.	Left.	Aspirated three times; twice serum, once pus.	May, 1880.	Improved for a time, then developed phthisis.	Died in the autumn.	The lung never dilated satisfactorily.
5	M.	14	Dr. J. L. Sullivan.	2 months.	Right.	Aspirated five times.	June, 1881.	Lung dilated rapidly.	Tube removed on twenty-third day.	Operation without ether. Only one tube introduced.
6	M.	22	Dr. J. W. Elliott.	Uncertain.	Left.	- -	June, 1881.	Lung did not dilate well.	Died at end of eight months.	Operation without ether, at the time regarded as palliative, as phthisis evidently existed.
7	F.	11	Dr. Chandler. Dr. F. I. Knight.	3 months.	Left. Apex beat under right nipple.	Aspirated twice.	July, 1881.	Heart in normal place, and respiration to the base of the chest twenty-four hours after operation.	Tube removed on thirty-eighth day.	Complete recovery.
8	M.	33	Dr. B. S. Shaw.	4 years.	Left. Heart beat only above right nipple.	Aspirated five times; four times serum, once pus.	August, 1881.	Lung never showed a sign of dilating.	Died suddenly on fifty-first day.	In this case two gallons of pus by measurement obtained at the operation. Autopsy refused.
9	M.	24	Dr. G. C. Shattuck. Dr. F. C. Shattuck.	3 weeks.	Right.	Aspirated once. Fetid pus.	December, 1881.	Chill after operation. Normal temperature after fourth day. Lung dilated rapidly.	Tube removed on twelfth day.	This patient had pneumonia in the newly expanded lung soon after the pleural cavity closed, but with no reaccumulation of pus. He made a good recovery from it. Seen one year later with lung in perfect condition.
10	F.	29	Dr. H. W. Broughton. Dr. H. I. Bowditch. Dr. F. H. Williams.	1 month.	Right.	Aspirated once. Fetid pus.	March, 1882.	Lung dilated well.	Tube removed on thirtieth day.	Opening quickly closed. No further trouble in the pleura.
11	M.	4	Dr. G. W. Snow. Dr. F. I. Knight.	1½ months.	Right.	Aspirated three times.	April, 1882.		Tube removed on forty-ninth day.	Opening quickly closed.
12	M.	3½	Dr. Hildreth. Dr. Dow.	5 weeks.	Left.	Aspirated once for diagnosis.	June, 1882.	Rapid dilatation of the lung.	Tube removed on thirteenth day.	Perfect recovery.
13	F.	26	Dr. Newell. Dr. H. I. Bowditch.	6 weeks.	Right.	Aspirated twice.	April, 1883.	Lung dilated rapidly.	Tube removed on twenty-sixth day.	Opening quickly closed.
14	M.	5½	Dr. J. A. Dow.	2 months.	Right.		June, 1883.	Lung dilated rapidly.	Tube removed on tenth day.	Opening quickly closed. Lung fully restored.

Of these fourteen cases, three died and eleven recovered.

Two of the fatal cases succumbed to phthisis, and in the remaining case the effusion had existed so long (four years) that the lung was without doubt converted into a mere fibrous cake at the top and back of the chest, and was totally unable to expand. The final cause of sudden death is unknown.

In all of the successful cases the empyema was of tolerably recent origin, so that in none of them was the lung disabled. The expansion of the lung was ordinarily very rapid. In Case VII., for instance, the heart had returned to the normal position and the lung had filled the chest at the end of twenty-four hours, and this, too, in spite of the fact that the disease had existed for three months. This rapid dilatation can, I think, be fairly ascribed to the suction power of the dressing which I have above discussed. The average time that the tube remained in the chest was twenty-four days, and this low average cannot be accounted for by the influence of the children (who notoriously do well) upon the statistics, for the average for the four adults is the same (twenty-four days).

These figures, when compared with the statistics of

the results of other methods of treatment, will go far to illustrate the advantages of the dressing I have described, and I feel sure that to obtain these results the mechanical action of the dressing must be intelligently regarded.

Dr. William C. Dabney, in the *American Journal of Medical Sciences* for October, 1882, in an article entitled *The Treatment of Empyema*, gives a summary of his conclusions as to the value of various methods of treatment, and says in a final clause that "Listerism would probably be advisable in city or hospital practice, but is of doubtful efficacy in the country, and under no circumstances should be allowed to interfere with through drainage."

This conclusion might be true if the only advantage of the Lister dressing were in the avoidance of septic infection. But if we consider the mechanics of the closure of these cavities, and seek to assist the expansion of the lung, we shall find the close antiseptic dressing a powerful aid in bringing about favorable results.

REMOVAL OF THE TUBE.

One of the two tubes introduced at the time of operation is best removed when the clots have all es-

caped and the discharge is reduced to about one fluid drachm in the twenty-four hours. The last tube is to be finally left out when the discharge dwindles to a few drops a day, when in short it is no more than would come from the sinus in which the tube lies.

I think the introduction of long tubes (catheters and the like) for injection of the cavity, as recommended by Fraentzel, is to be avoided, as you thereby separate the pleural surfaces already adhering and obliterating the cavity.

THE FETID CHARACTER OF THE PUS.

In the three cases in which the pus was fetid the recovery was not in the least interfered with by this circumstance. Two of these patients had a chill soon after the operation, but no ill effects followed it, the temperature rapidly fell to normal and stayed there. The odor disappeared in all of them after the third or fourth dressing, and recovery was uninterrupted.

ANTISEPTICS EMPLOYED.

At first I used carbolic acid exclusively as an antiseptic, but soon substituted chlorinated soda for it as an injection into the chest, using a solution such as described above. This proved so satisfactory that I later substituted it entirely for carbolic acid in the spray and various solutions, still continuing, however, to use carbolized gauze as a matter of convenience, it being easily obtained, and never giving rise to carbolism.

To show how small an amount of carbolic acid will cause poisonous symptoms in these cases I would cite Case XII. In operating upon this boy, four years of age, chlorinated soda was used for the spray and for moistening the inside dressings, but as chlorinated soda corrodes the instruments I laid them and the rubber tube in a carbolic solution, one part to thirty of water. This I also used to wash the boy's side before operating, and to cleanse my own hands. The minute quantity of carbolic acid which was conveyed to the wound by the instruments, tubes, and hand of the operator sufficed to cause frequent vomiting on the day after the operation, and to give the urine a dark, smoky color.

THE USE OF INJECTIONS INTO THE CHEST.

Professor Lister advises against the use of injections, and regards them as unnecessary. For the simple removal of the pus injections are certainly not needed, but in those cases in which there were purulent clots in the chest I found injections of the greatest service in removing them, and their complete expulsion is very important, as they keep up enough irritation to cause a continued secretion of pus, which quickly ceases when they are gotten rid of. When the pus is fetid, injections not only hasten the disappearance of the fetor, but speedily relieve the fever following the operation.

In using chlorinated soda for injections it will be noticed that if a strong solution be used it forms coagula with the serum. By the use, however, of a solution containing one part of liquor sodæ chlorinatæ to twelve or fifteen parts of water this may be partially avoided, and the coagula are then so soft and gelatinous that they readily escape through the tubes, and cause no trouble.

QUESTION OF OPERATION IN PHTHISICAL PATIENTS, OR WHEN THE LUNG HAS BEEN LONG COMPRESSED.

It seems as if little good were to be expected from making a free opening into the chest when the existence of phthisis is clearly proven, as such a case is unavoidably fatal, and the opening, if it is of any avail, only unnecessarily prolongs the sufferer's last days with the added distress of a disagreeable discharge from the side. Aspiration to relieve urgent dyspnoea is the only proper operative procedure in such cases.

Data are as yet insufficient to decide how long a lung may be compressed and yet recover and dilate to fill the chest when the pressure is removed. In our series two cases in which the compression had existed for three months rapidly recovered when the fluid was removed. On the other hand I have seen the lung reduced to a fibrous cake without a vestige of proper lung tissue by two years of compression. Cases of course will differ greatly in this regard, and it would be well in a doubtful case to aspirate several times, and carefully watch the lung, and if noticeable dilatation follows the aspirations finally to establish a free opening. If no dilatation occurs frequent aspiration may be sufficient to relieve dyspnoea, and eventually to bring about closure of the cavity by collapse of the chest wall and approximation of the neighboring organs. If, however, the pus constantly reaccumulates, and gradual exhaustion threatens a fatal issue, a free incision and the resection of portions of several ribs are clearly indicated to allow the further collapse of the chest and closure of the cavity.

METHOD OF OPERATING.

In regard to the point selected for the opening, I almost invariably opened the chest in the eighth, occasionally in the seventh, intercostal space, just in front of the latissimus dorsi muscle. This place offers several advantages: the chest wall is here thinly covered by muscles; the opening is dependent in any ordinary position of the body except when lying on the other side, and yet is not so far behind as to be directly pressed upon when the patient is on the back; it is not so low as to be interfered with by the diaphragm even when this is considerably pressed upwards, as it may be after the fluid is out; it is far enough from the shoulder to allow a good dressing to be applied without interfering with the arm.

Lastly a word as to the technique of the operation.

In opening the chest near the base there is always danger of injuring the diaphragm or even, as has occurred, the abdominal organs, and the preliminary introduction of an aspirator needle is a common precaution to gain assurance of the presence of pus at the point selected. In some of my first cases I used a grooved needle for this exploration, and when pus was found, the groove of the needle guided the knife directly into the cavity, and in withdrawing it an incision of proper length could be made. The only drawback to this method was that with an ordinary grooved needle the elastic skin closed into and filled the groove, and thus prevented the pus from readily showing itself. To avoid this I had the needle, figured at the end of this article, made for me by Codman and Shurtleff, instrument makers. It is like an aspirator needle, with a slit upon one side wide enough for the point of the knife to slip along. This form makes it impossible for the skin to press into and oc-

clude the groove, and the pus always escapes readily along it. The handle is set at an angle to allow the ready use of the knife beside it. After the opening is made with the knife a director is slipped in, and the sharp needle removed. If after the incision one

instrument is withdrawn before another is introduced a slight shifting of the muscles may close the opening, which is then difficult to find again. The operation done thus with an exploring needle is finished ordinarily in a few seconds, and the pain is reduced to a minimum, an important consideration when ether cannot be administered.

MINOR INJURIES OF THE SPINAL CORD.¹

BY BENJAMIN H. HARTWELL, M. D., OF AYER.

THE subject presented for consideration to-day comprises a class of diseases arising from slight injury to the spinal cord, and is based upon the notes of nine cases, in which both the injury and the force used to produce it were slight. Five of the nine were passive or subacute hyperæmia, and four a mild form of chronic myelitis. These cases were of from two to twenty years' duration, and were not severe enough to prevent a certain amount of labor being performed.

Erichsen, in his work on Concussion of the Spine and Nervous Shock, says: "The primary effects and secondary results of slight injuries to the nervous system do not appear, as yet, to have received that amount of study and attention on the part of surgeons that their frequency and importance alike demand." These minor injuries are of special interest to us, as practical physicians, from their comparative frequency, their liability to result in permanent change in the substance of the cord, and because we can do much in the way of relief and cure by appropriate treatment.

Their importance in a medico-legal point of view is at once recognized; for while there could be no doubt of its gravity if the injury were severe, in the form under consideration there is not only no external sign, but a limited time may elapse without symptoms, of injury. The question presents itself here, as to whether we have in every case of injury to the cord sufficient evidence—objective symptoms—to enable us to determine the fact. Dr. R. M. Hodges² says: "The symptoms of actual organic changes in the spinal cord, when they follow concussion, are by no means vague and obscure manifestations. They are objective, and admit of recognition and appreciation. They are incapable of being simulated with an accuracy which will permit of long deception. The subjective symptoms following alleged concussion of the spinal cord

are ill defined, vary in degree and character, and such as permit of ready simulation. If objective and subjective symptoms are both present in any one case, as not infrequently happens, the objective symptoms predominate." Hamilton³ says: "I do not think that any jury should give damages unless some physical signs of actual spinal disease are present." While I would not like to take the position absolutely that the objective symptoms are well marked in every case of so called concussion, it must be rare indeed for a doubt to remain in the mind of one who has watched a case from the beginning. Those vascular disturbances which act as a cause of the symptoms in these cases, and which may be followed by inflammation, or changes in the substance of the cord, must soon produce a train of symptoms by which the lesion can be recognized.

CASE I. J. B., aged forty-four, a strong, able-bodied man, was shaken in a railroad accident, but not thrown from his seat. He was seen within a few minutes, and complained of pain in the lumbar spine and numbness in the extremities, chiefly on the right side. There were no external evidences of injury. The temperature, pulse, and respiration were normal. The catheter was used twice in the first twenty-four hours, but not afterwards, though he seemed to have a good deal of difficulty in starting the urine. The bowels were constipated. No special change took place until the tenth day, when there was a dusky, mottled appearance of the skin over the upper portion of the body, rapid breathing, cardiac murmur, intolerance of light, and muscular twitching. He stated that the left hand felt as if encased, that there was a band feeling around the left half of the body under the nipple, that he was unable to see plainly, and had a severe pain in the back of his head. He could move the left arm and leg better than the right, and there was some anaesthesia, more marked on the right side. This condition, changing to better then worse again, remained for several weeks, when improvement commenced, with the probability of perfect recovery.

In this case the objective symptoms were sufficiently prominent for us to pronounce it an injury of the right half of the cord.

In another case, where a locomotive demolished a carriage containing a young lady, and threw her some distance along the side of the track, she remained standing while being subjected to a thorough examination in view of possible litigation. There was no complaint of pain in the back, and not till the fourth day did symptoms denoting spinal injury show themselves, when she grew rapidly worse, was confined to the bed, but after five years has made a partial recovery.

That form of spinal injury produced by concussion, or the jar of the railway carriage, is an interesting one in view of the increasing number of men who by occupation are compelled to maintain an erect position for from six to twelve hours a day, subjected to the constant jar of the carriage. Hamilton⁴ mentions cases of subacute spinal hyperæmia occurring among city car drivers; and Hodges,⁵ in the paper referred to, speaks of the jar to which railroad men are exposed as being sufficient to produce nervous disease. The trifling jar seems necessary to produce hyperæmia, position alone not being enough. In Cases II. and III. a rough ride aggravated all the symptoms, while any position in

¹ Read at the Annual Meeting of the Massachusetts Medical Society, June 12, 1883, and recommended for publication by the Society.

³ Nervous Diseases, 2d edition, page 271.

⁴ Loc. cit., pages 256, 257.

⁵ Boston Medical and Surgical Journal, April 21, 1881, page 365.

which the jar was removed gave comparative relief. Spinal hyperæmia is favored by the peculiarity of the circulation of the blood in the spinal canal; and we can readily understand how blood stasis, to a certain extent a natural result of these anatomical conditions, can become abnormal. Jaccoud says that the tortuous course of the veins and the absence of valves favors it. Bartholow¹ puts the arterial and venous capacity as one to four; that is, the capacity of the veins is four times that of the arteries.

CASE II. Mr. S., locomotive engineer, sixteen years on the road. General health good. After six years of service there was a sense of weakness and easy fatigue in the feet and legs, and pain in the back and head after hard drives. These symptoms gradually grew worse, and seven years after his condition was as follows: Temperature, pulse, and respiration normal. There was pain more or less constant, described as a "hard ache," extending from the sacral region up the spine, and through the head to the supra-orbital region. There were numbness, prickling, and formication in the extremities; the first two most noticeable below the knees, the latter on the back of the neck. The feet and hands were cold, the legs felt as if made of wood; at times, when the pain was excessive, he would stagger in walking, and in the dark had a constant fear of running into a post or other obstacle, so that it was his custom to walk in the middle of the street. If he stepped too heavily, or struck his hand firmly against an object, he would feel the blow in his head. He told me that he had stood on his toes during many miles of travel to avoid the jar. There was frequent urination. The rectum was not involved. He saw flashes of light, and sometimes felt as if a shade were placed directly over the eyes. There was lack of coördination; at times he could see best with one eye closed, it made no difference which one. There was some tenderness on deep pressure over the last cervical and first dorsal vertebræ. The cincture feeling was not present. Tendon reflex was natural. Ergot and belladonna were given in full doses; the latter afforded the most relief. After two months of rest he resumed his place on the engine, though not fully relieved; at the end of a year restoration to health seemed to be complete, and remains so after three years.

CASE III. Mr. M., conductor, has been on the road seventeen years. His physical condition is good. About seven years ago he commenced having pains in the lumbar region, and irregular pains down the left leg, with prickling and formication. When I saw him the trouble had increased, and involved both legs, the prickling and formication being most noticeable on the plantar surface of the feet and across the upper surface of the toes. There was occasional stiffness of the ankles, from muscular rigidity, and a feeling described as that of walking on a thick Brussels carpet, which would sink under the feet. There was a good deal of pain in the lumbar spine, and irregular pains radiating down both legs to the feet. These symptoms were always worse after a hard day's work, a long walk, a ride on the horse cars, and in hot weather. They were not present, as a rule, during the first part of a day after a night of rest. Latterly there have been some muscular cramps in the left leg, and the trouble seems to be extending. There is slight tenderness over the first lumbar vertebra. The pain in the leg is relieved in a

measure by strong flexion without regard to the position of the body. This case has but recently come under treatment.

The above were two cases of passive or subacute hyperæmia, the first involving the cervical, and the last the lumbar, enlargement of the cord. They were caused by the continued jar of the railway car, irrespective of any injury that might by its effects upon any portion of the spinal medulla predispose it to lesions of this kind. To what extent these diseases prevail among railroad employees I am not able to state, but a somewhat extended inquiry leads to the belief that they are more rare than has been claimed by some authorities.

Backache is said to be a common complaint among the class of men referred to, but I am ignorant of its cause, — whether it is muscular, in the sacral plexus of nerves, or depends upon an increased amount of blood in the spinal canal. In view of the cases just mentioned, which for the first few years were only indicated by an occasional backache, pain in the back among railroad men demands the closest investigation.

Most of the cases of which I have notes were caused by slight concussion, blows or other means, which produced no external signs of injury. The patients were able to attend in part to their daily duties. With some the trouble excited but little attention for months, although they were conscious of its effects, and gave a clear history back to the time when the injury was received. Rosenthal says: "In order to recognize the initial symptoms of myelitis we must pay strict attention to the first peripheral symptoms of medullary irritation. These are vague neuralgic pains, which are often unrecognized, or wrongly interpreted, circumscribed sensation of cold or numbness in the limbs, circumscribed anæsthesia, etc."

The following cases will serve to illustrate: —

CASE IV. Mr. P., twenty-three years ago, was injured in the United States service. While carrying one end of a long box the opposite end was dropped, and he felt the shock in the lower part of the spine. He served out his term of enlistment, and has since worked at his trade, that of cabinet maker. From the time of the accident he has had more or less pain in the back, prickling and numbness in both legs, chiefly in the soles of the feet, and a cord-like feeling from the superior spinous processes of the ilia around the back. For the past three years he has felt as if a cushion were interposed between the bottoms of the feet and the ground, the legs have felt heavy, and the toes have scraped the ground more or less in walking. He is apt to trip upon a stone or uneven surface. There is a good deal of muscular atrophy. The general health is good, though he has lost about thirty pounds in weight during the last few years. The bladder and rectum are not involved. Tendon reflex is absent in the left leg, and very slight in the right. There is some tenderness on deep pressure over the first lumbar vertebra. The most pain is experienced, and all of the symptoms are aggravated, after the completion of the work of the day. The best sleep is obtained during the first hour or two of the night, after which the position is frequently shifted, and the sleep disturbed by pain. Strongly flexing the legs and thighs gives some relief to the pain. He is worse during hot weather.

CASE V. A young, able-bodied farmer received an injury in the lower dorsal region by the sudden turning

¹ Medical News, December 16, 1882, page 673.

of a plow, caused by its striking a stone. He did not consult his physician for a year after the accident, although he felt pain from the first. At the end of two years his condition was much like that of Case IV., except that it was milder in degree. At no time had he given up the management of his farm, though compelled to obtain help for the harder portion of the work. In the course of a year cure seemed to be complete. He remains entirely well at present, three years after recovery, having in the mean time performed the hardest kind of farm work. Treatment consisted of moderate exercise, dry cups on each side of the spine opposite the lumbar enlargement, night and morning; galvanism; one half, increased to one, teaspoonful of the fluid extract of ergot, three times a day, occasionally combined with belladonna. The same treatment has been applied to Case IV., always with an amelioration of symptoms for a while, but circumstances over which I have no control prevent its being carried out satisfactorily; and, though still under treatment, the probability is that there will be a gradual increase of the disease.

The symptoms in these cases point, with hardly a doubt, to transverse lesions of the lumbar enlargement of the spinal cord. Case IV. is probably one of chronic myelitis, with impairment of the functions of the gray matter, and that the trophic function is becoming affected is shown by the muscular atrophy. Case V. is one of passive hyperæmia. Erb¹ says that "Hyperæmias do not always extend over the entire spinal canal, but often are confined to the cervical, or lumbar, or other portions;" and again, "in a few cases something is seen which lies between the condition of congestion and that of inflammation." The line between hyperæmia and myelitis is probably an artificial one; they may be regarded as different stages of the same disease. Profoundness of the disturbances of sensation and motion is perhaps the best point to judge by at first, if we are to make a distinction between them, and later the result of appropriate treatment, cure only resulting when hyperæmia alone exists. Therapeutically it makes no difference, as the treatment would be the same whether we have before us a case of passive hyperæmia or a mild form of chronic myelitis.

The early symptoms of some of these cases are like those of sciatica. Case III. was markedly so, the only complaint for the first three or four years being pain in the back and left leg. The location of the spinal lesion explains this, for Ranney,² in a diagram giving the relation of the spinal cord, nerves, and vertebræ, shows that the sciatic nerve rises from the lower portion of the lumbar enlargement of the cord, opposite the twelfth dorsal and first lumbar vertebræ. Tender points along the course of the nerve will help to distinguish a simple neuralgic affection; moreover, in congestion and inflammation, before many of the characteristic signs appear, there will be an aggravation of the symptoms after continued exercise, prolonged recumbent position, and during the latter part of the night and first part of the day; again, these cases are usually worse in hot weather. A history of injury to the back is so common that to be of value in diagnosis it must correspond to the appearance of first symptoms.

Reflected troubles, and those of a hysterical character, must be carefully excluded. In a case (not included in the nine) with a history of injury, and many

of the symptoms of spinal hyperæmia, complete relief was obtained by the removal of some vascular growths from the uterus with the curette. Trial of remedies will sometimes assist in diagnosis. In progressive cases, that is, in all acute cases, and in cases chronic as regards time, but in which there is locally an active state of the circulation, strychnia does harm, while ergot and belladonna will usually give relief to the distressing symptoms. In functional cases, on the contrary, and in those old chronic ones characterized by debility and loss of muscular power, strychnia almost always does good, and is sometimes very effective.

Some of the cases of minor injury of the spinal cord fully recover, others remain greatly relieved, and a few relapse into almost helpless cases of chronic myelitis. In the latter the change is frequently sudden. Those that get well are probably only hyperæmia. Of the nine cases which form the basis of this paper (the cases of concussion from railroad accident are not included), three remain cured after the lapse of several years, three are still under treatment, with a prospect of cure in one, one is gradually growing worse, one remains better than before treatment, and one, after seemingly being relieved of passive hyperæmia for two years, had a sudden lighting up of the disease, without apparent cause, and is a helpless invalid. The cincture feeling was present in all of the above cases, except the two caused by jar of the railway carriage; and, again, excepting these two, all were aggravated by the recumbent position maintained for more than a few hours at any one time. One voluntarily assumed the knee-chest position in bed to obtain relief from pain. As a rule, reflex excitability and electric contractility were not markedly changed; if at all, they were increased, though in Case IV. they were almost entirely absent, more so in the left than right leg. In a case of syphilitic myelitis, now under treatment, simply touching the bottom of either foot brings about spasmodic movement in both legs.

This paper would not be complete without giving an outline of the treatment which has been found beneficial in the above class of diseases of the spinal cord. Rest is of the first importance, not absolute in the recumbent position always, but in the sense of relief from care and ordinary duties. As previously mentioned, the patients in all of the nine cases noted were, at the time application was made for relief, engaged more or less actively in labor; and, although in two or three of them treatment was carried on without change in this respect, still it was much more satisfactory when partial or complete suspension of work was obtained.

Ergot and belladonna, as recommended by Brown-Séquard, have been found to be remedies of undoubted efficacy. Belladonna is more prompt in its action, especially when there is some vesical complication. Ergot is of most value when given in large doses, and long continued. The latter, usually in a few days, affords some relief to the intense pain in the back; the former, given so as to produce its full medicinal effects, in many cases stops all pain for the time, and if continued has a permanently good effect. In acute cases ergot seems to do harm, and digitalis, acornite, and bromide of potassium should be given instead. In Case I. ergot aggravated the symptoms on two trials, while the good effect of digitalis was seen, to a certain extent, within a few hours after administration. Bartholow³ says: "Its [ergot] administra-

¹ Ziemssen, vol. xiii., p. 203.

² Applied Anatomy of the Nervous System, page 340.

³ Medical News, December 16, 1882, Clinical Lecture.

tion in spinal inflammation is improper, because of the peculiarity of its action. It induces an anæmia of the arterial distribution, — an ischæmia, properly speaking, — but the blood thus driven from the arterial side accumulates on the venous side." Sponging the spine with water as hot as the patient can bear it, the sponge being drawn rapidly along the whole length of the spine for ten or fifteen minutes morning and night, with the daily application of an irritant to the same surface, does good in either the acute or chronic forms of the disease under discussion. Peripheral irritation surely has some effect upon the nutrition of internal organs, especially when these organs are placed in direct anatomical relation to the surface. The results published by Strumpf, of the treatment of spinal sclerosis by the faradic brush, are strong proofs of the power of mild peripheral irritation.

Galvanization has been proved to act upon the cord itself, and is one of the best agents that we have in the treatment of the chronic form of spinal troubles. Unfortunately, in private practice in the country it is impossible to use it in every case with that frequency and perseverance necessary to produce good results. In one case it seemed to aggravate the symptoms; in the few others in which it was used it was undoubtedly a help. Dry cups, placed on each side of the spine, once or twice daily, are means which should not be omitted in the treatment of any form of spinal congestion or inflammation. In addition, the patient should be placed in the best possible condition as regards his surroundings, diet, clothing, amount and nature of exercise, avoiding dorsal decubitus, but resting upon the side, or with elevation of the body, shoulders, and head, as may be determined by trial to give the most relief.

There are other remedies of known value, but the above have been applied in the treatment of the cases considered in this paper.

FIBROMA OF THE VAGINA.

BY EDWARD T. CASWELL, M. D., PROVIDENCE, R. I.

In the number of this journal for July 19, 1883, Dr. Davenport, in his report on Recent Progress in Gynæcology, refers to an article of Professor Kleinwächter's upon Fibromata and Myomata of the Vagina, in which the latter states that he has been able to collect but fifty cases of these tumors recorded in medical literature, and adds to these three of his own. As eight days previous to the above date I had operated upon a case of fibroma, which had been the first of my own experience, and as from the above statement I conclude that such growths are at the least not common, I venture to place it on record.

The patient was a young lady, who was soon to be married, and who had been aware of some obstruction in the passage for about two years. Latterly the obstruction had seemed to increase. There had been no pain, and no disturbance of the menses. Some inconvenience was experienced in walking, and some in sitting. On examination I found a tumor in the middle line of the anterior wall, over the course of the urethra, as large as a pigeon's egg, its anterior extremity being about three quarters of an inch back of the meatus. It was not sensitive to pressure, and had a slightly elastic feel. An operation was advised for many reasons, not the least of which was the relief from anxiety that it would afford the patient in view of her approaching marriage.

A single incision in the middle line enabled me to easily enucleate the tumor, which measured in its long diameter about one and a half inches, and about three quarters of an inch in each of its other dimensions. Under the microscope it proved to be a fibroma. There was but little hæmorrhage, and the wall of the urethra was uninjured. Two or three sutures of catgut, with a small piece of drainage tube, some absorbent cotton, and a napkin, was all that was required in the way of dressing. Carbolyzed injections were freely used, and the catheter passed for three or four days. The tube was removed on the third day. The recovery was uninterrupted, save for a slight hæmorrhage on the day after the operation, which was checked by an injection of hot water. The wound was entirely healed by the eighth day, and the patient dismissed on the tenth. Except for the slight discharge of the first few days the young lady was conscious of no departure from her usual condition of health.

REPORT ON PROGRESS IN THE TREATMENT OF DISEASES OF THE THROAT.

BY F. I. KNIGHT, M. D.

TUBERCLE OF THE LARYNX AND LUNGS WITH CANCER OF THE STOMACH IN THE SAME PATIENT.

DR. SCHIFFERS¹ showed the larynx at the Medico-Chirurgical Society at Liège. The patient had suffered from pulmonary tuberculosis and from gastric troubles. The posterior third of the left vocal cord was swollen and immovable; the right cord also was paralyzed. At the post-mortem examination, besides the usual tubercular lesions in the lungs, a cancerous tumor was found in the stomach near the pylorus, causing such a narrowing of the orifice as hardly to admit the tip of the little finger. The mesenteric glands were swollen and often caseous. The larynx presented a large tuberculous cavity affecting principally the posterior part of the left vocal cord.

ANEURISM OF THE AORTA CAUSING BILATERAL PARALYSES OF THE VOCAL CORDS.²

The physical signs of aneurism were not well marked, but the laryngoscope showed complete paralysis of both abductors of the vocal cords. Tracheotomy was performed without relief to the dyspnoea. Autopsy showed an aneurism, as large as the fist, of the descending aorta, flattening out the left recurrent nerve, but the right nerve was at some distance, and apparently unaffected. The cardiac plexus, however, had been compressed between the trachea and aorta.

Two similar cases are recorded in the Pathological Society's Transactions by Drs. Bäumlér and George Johnson,³ but in these cases there was no note of any pressure on the cardiac plexus.

ARREST OF ACUTE CORYZA.

According to Dr. Gentilhomme⁴ sulphate of atropia (from a quarter of a milligramme to one milligramme) given as a pill has an immediate effect on the first stage of coryza, often arresting the progress of the disease. It also produces great relief when the coryza is confirmed, but its action is less remarkable than at the

¹ Ann. de la Soc. Med. Chir. de Liège, June, 1882, and London Medical Record, October 15, 1882.

⁴ Rev. Med. Française et Étrangère; London Medical Record, October 15, 1882.

beginning of the inflammation. When bronchitis exists at the same time the remedy produces an equally favorable effect on the bronchial mucous membrane. The employment of atropia is based on the fact that it has the power of diminishing the nasal mucous secretion even to the extent of completely drying it up, and at the same time it acts upon the vessels by relieving their congestion. [This use of belladonna has long been known, but is, perhaps, too much confined to homeopaths at the present time.]

ON THE POSSIBILITY OF INTRODUCING A TUBE INTO THE LARYNX WITHOUT PRODUCING PAIN OR ANY REACTION.

Dr. Brown-Séquard¹ announces that he has discovered the following facts: After exposing the larynx of animals by an incision in the side of the neck, a current of carbonic acid being applied for a short time (fifteen seconds to two or three minutes), the sensibility of the larynx is completely lost, so that a tube or the finger (in case of a large dog) could be introduced and moved about without producing any reaction. This local anesthesia lasts from eight to ten minutes. No bad effect followed either general or local. Farther experiments are necessary to determine whether sufficient carbonic acid can be used locally to produce anesthesia in man without danger. These Dr. Brown-Séquard proposes to make.

FOREIGN BODIES IN THE AIR-PASSAGES.

Dr. Weist² publishes a very interesting communication on this subject. The paper is based on 1000 cases, 897 of which are reported as never having been published. Dr. Weist draws from a study of these cases a different conclusion in regard to the propriety of bronchotomy from that generally held at the present day, which he states to be that, as a general rule, "the certainty of the presence of a foreign body in the air-passages makes bronchotomy necessary." This rule rests principally on the statistical tables of Gross and Durham. Dr. Weist says that these tables certainly seem to afford a sufficient basis on which to rest the conclusion that in cases of foreign bodies in the air-passages bronchotomy offers a far better chance of recovery than waiting for spontaneous expulsion. Adding the cases of Gross and Durham together the result is a total of 722 cases; 356 without operation, with 59.55 per cent. recoveries, and 40.49 per cent. deaths. With the operation 366 cases; of these 76.77 per cent. recovered, and 23.22 per cent. died, a difference of 17.22 per cent. in favor of the operation.

Dr. Weist, in 1867, collected and published a table of 163 cases, the results of which were so greatly at variance with those heretofore published that, on the advice of Professor Gross, he was led to continue the collection of cases. Hence the present large table with so many cases never published before. In 63 cases the foreign body was removed by operative measures other than bronchotomy, for example, with forceps, with or without the aid of the laryngoscope. These are excluded in calculating the chances of recovery afforded by bronchotomy compared with those by following the plan of non-interference. There remain 937 cases; of these 599 were not subjected to bronchotomy; 76.79 per cent. recovered, and 23.20 per cent. died. Bronchotomy was performed in 338 cases; 72.48

per cent. recovered, and 27.42 per cent. died, a difference in favor of non-interference of 4.31 per cent. As a result of the study of the combined cases of Gross, Durham, and Weist (1674 in all) it appears that without operation there is one death in 3.5 cases, and one in 4 after bronchotomy.

Dr. Weist says that in presenting these facts he is not seeking to bring bronchotomy into discredit in cases of foreign bodies in the air-passages. In a large number of cases the larynx or the trachea must be opened to save life. He is striving to show that the present accepted rule is too broad; that in many cases when it is certainly known that the trachea or bronchia contain a foreign body the patient will be more likely to recover if trusted to the chance of spontaneous expulsion than he will if subjected to operation. Then Dr. Weist goes on to help determine in what cases bronchotomy should be performed. [It seems to us that this difference in cases furnishes the clew to the results in the tables, and makes them of little value in the light in which the author regarded them. It is fair to infer that the bronchotomy class included all the difficult cases, and the other all the easy ones, that is, where the body was soon expelled spontaneously or caused little disturbance.] The author says that when the nature of the foreign body is known the propriety of an operation can be more easily determined than when it is not, as it is apparently settled that some substances are more easily expelled than others. Seeds are more easily expelled than other substances usually lodged in the air-passages. Dr. Weist shows from his tables that spontaneous expulsion of seeds and recovery took place in a larger per cent. than in the cases subjected to bronchotomy. [We fail to see the point of the argument in this; as a rule, probably, only those where spontaneous expulsion had not taken place, and symptoms were urgent, the hard cases, were subjected to the operation.]

It very rarely happens that a surgeon sees a case of this accident during the paroxysm of strangulation that immediately follows the introduction of a foreign body into the air-passages. Whenever the symptoms continue urgent, or attacks of threatening suffocation come on frequently, bronchotomy should be resorted to without unnecessary delay, provided that direct extraction is not practicable.

Dr. Weist draws the following conclusions from a study of these cases:—

(1.) When a foreign body is lodged either in the larynx, trachea, or bronchi the use of emetics, errhines, or similar means should not be employed, as they increase the sufferings of the patient, and do not increase the chances of recovery.

(2.) Inversion of the body and succussion are dangerous, and should not be practiced unless the wind-pipe has been previously opened.

(3.) The presence simply of a foreign body in the larynx, trachea, or bronchi does not make bronchotomy necessary.

(4.) While a foreign body causes no dangerous symptoms bronchotomy should not be performed.

(5.) While a foreign body remains fixed in the trachea or bronchi as a general rule bronchotomy should not be practiced.

(6.) When symptoms of suffocation are present or occur at frequent intervals bronchotomy should be resorted to without delay.

(7.) When the foreign body is lodged in the larynx,

¹ La France Medicale, October 3, 1882.

² American Practitioner, August, 1882.

there being no paroxysms of strangulation, but an increased difficulty of respiration from œdema or inflammation, bronchotomy is demanded.

(8.) When the foreign body is movable in the trachea, and excites frequent attacks of strangulation, bronchotomy should be performed.

EXTIRPATION OF THE LARYNX.

Professor Burow, of Koenigsberg, has a very interesting paper on this subject in the *Archives of Laryngology* for April of this year. As a résumé he lays down the following points:—

(1.) Total extirpation of the larynx in cases of carcinoma has as regards danger to life, as well as in the matter of absolute cure, given hitherto little encouraging results, forty per cent. of the cases eventuating in death after the operation, these figures swelling to seventy per cent. of cases of death due to a relapse of the disease.

(2.) Notwithstanding this operative essays in this direction should be continued with the following restrictions: (a) the patient's age should not exceed sixty years; he should be comparatively strong, and free from serious complications; (b) the disease must be confined to the larynx, the surrounding glands, muscles, etc., being unaffected.

(3.) In all other cases where dyspnoea is present tracheotomy should be promptly performed.

(4.) The prognosis in cases of sarcoma is much more favorable. Benign tumors encroaching on the calibre of the larynx to a marked extent might also furnish an indication for the operation.

(5.) Syphilitic processes, necrosis of the cartilages, and papilloma do not call for total extirpation of the larynx.

(To be concluded.)

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M. D., SECRETARY.

MAY 9, 1883. The meeting was called to order at 8.05 o'clock by DR. G. B. SHATTUCK, chairman.

No pathological specimens being offered for exhibition, the first business was the reading of a lengthy and valuable paper by DR. A. T. CABOT, entitled

CASES OF EMPYEMA, TREATED ANTISEPTICALLY.¹

but which was in reality a most interesting and instructive contribution to the surgical treatment of this disease, aided by antiseptic precautions, and resulting in a percentage of recoveries, and a diminished period of treatment which seems most astonishing when we remember the usual progress of convalescence from this affection, even in uncomplicated cases, under the treatment which has been generally adopted for their relief.

DR. HARLOW asked how large the incision must be to accomplish thorough drainage from the chest and afterward to accommodate the drainage tubes?

DR. CABOT replied that the tubes employed were the largest which could be introduced between the adjacent ribs, and that the incision need only be large

enough to allow them to be introduced. The tubes should be long enough to reach the surface of the pleura, without projecting into the cavity of the chest. They thus cause no irritation, but provide for the complete and continuous drainage of the chest, which is at the same time protected by the mackintosh from any outward infection, thus ministering in every possible way to a speedy and perfect recovery.

DR. HARLOW asked if a solution of permanganate of potassa might not be employed as a disinfectant?

DR. CABOT replied that this had been used, and with good results, but he is fully satisfied with the solution of chlorinated soda, one part to twelve of water, which removes all the flakes of pus from the cavity of the chest, and is a thorough disinfectant without inducing poisonous symptoms, as carbolic acid is often prone to do. In one of the reported cases the use of carbolic acid for washing the chest previous to the operation, and for rendering the operator's hands and the instruments aseptic, was followed by symptoms of severe carbolic acid poisoning in the patient, which did not entirely subside for thirty-six hours. From the liability to this accident he has discarded carbolic acid and now employs the solution of chlorinated soda in all cases, and is well satisfied with the change.

DR. M. H. RICHARDSON spoke at some length in relation to a variety of tubes for drainage of the pleural cavity which are supplied with valves for the mechanical exclusion of air and impurities from the thoracic cavity while offering no resistance to the passage outwards of fluids from the chest. He had employed these tubes in several cases in which they might be expected to give good results if at all, but they had disappointed his expectations in every instance, causing unfavorable symptoms in all the cases, and utterly failing to act as barriers to infection of the pleural cavity from the outside of the body. Dr. Richardson said he entirely agreed with the views of Dr. Cabot in relation to the prognosis in the operation for empyema in phthisical subjects, as his experience in this direction had afforded an unfavorable course of the disease in every case operated upon. In these cases the lung did not expand after the chest was opened and the fluid liberated, but the cases drag on for years or die earlier from the development of some rapid form of phthisical disease.

DR. DRAPER asked how the time was determined at which the drainage tube should be removed. Is it regulated by the amount of discharge from the open end or by the character of the discharge? It has been a source of great uncertainty in thoracentesis to know when the opening might be allowed to close.

DR. CABOT replied that he removed the drainage tube at any time when he felt sure that the discharge was not more in quantity than that coming from the walls of the incision around the tube. The opening usually closed quickly and permanently.

DR. H. I. BOWDITCH regarded Dr. Cabot's antiseptic valvular method as a most invaluable addition to the present treatment of empyema. The rapid cures of Dr. Cabot's cases had convinced Dr. Bowditch of the value of Mr. Lister's antiseptic dressings. These, with the valvular appliances as prepared and used by Dr. Cabot in the cases reported, had been most convincing. Hitherto Dr. Bowditch had not felt assured of the great value of antiseptics, because he had seen many cases get well without them. It would seem from Dr. Cabot's results that the treatment of empyema, in

¹ Vide page 145 of this number of the JOURNAL.

proper cases, by a permanent opening, was about to become almost upon a par with aspiration in its simplicity and rapidity of result. Dr. Bowditch regarded with pleasure this latest step in the idea of removing fluids from the thorax; and certainly to one who can remember when that operation, even with an exploring trochar, was either sneered at or opposed by all as dangerous, the cases reported here to-night are most encouraging. Dr. Bowditch remarked upon the operation of injecting fluids into the chest, that we had often heard that it was dangerous; some physicians in fact, were unwilling to use them. Deaths had occurred in consequence. Dr. Bowditch had no such fear, provided proper precautions were taken. We must be careful never to inject so much as to cause the least dyspnoea or distress to the patient. If too much were thrown in, the heart or the healthy lung might be compressed, and thus the breathing or the circulation might be disturbed, or perhaps fatally obstructed.

In connection with this subject, Dr. Bowditch referred to the case reported¹ of a young girl in Glasgow who was taken ill September 24, 1882, and upon whom, October 14th and 19th, owing to orthopnoea and threatening fatal symptoms, aspiration was performed by Dr. W. T. Gairdner, of Glasgow. Seventy ounces of exceedingly fetid pus were removed on the 14th, and on the 19th twenty ounces, which was less fetid. On the 20th a free opening was made by Dr. Buchanan, professor of surgery. Two tubes of Gooch's double canula were introduced, crossing each other, and eight gallons of diluted Condy's fluid were allowed to flow in and out by a siphon apparatus. This, of course, made little or no pressure on the internal organs, but simply washed out the pleural cavity till the fluid came out as pure as it entered. A large tube for drainage was then inserted. In five weeks the discharge ceased and the patient was well. Dr. Gairdner said the case was unique in his experience. Dr. Bowditch had never seen one comparable with it. Though Dr. Cabot's valvular plan was not followed in that case, Dr. Bowditch regarded the free and safe method pursued in injecting antiseptic fluid and the large opening as important factors in the cure.

Dr. A. N. BLODGETT remarked that to any one who had observed the ordinary course of recovery in a case of operation for the relief of empyema as this was formerly done, the history of the present cases cannot fail to be very interesting. He recalled a case, well known in its time, which occurred in a boy of thirteen under the care of Dr. Minot. The operation was performed with all known precautions, and the case eventually did well, recovering completely, which condition still exists, and the patient is a strong and vigorous farmer. The course of the disease was, however, vastly different from the cases reported by Dr. Cabot. The discharge continued purulent for months, the patient became much exhausted, and suffered from hectic and night sweats, and for a long time was in a condition to excite grave apprehension. The tube was small but long, and of silver, and was not permanently removed until months after the operation. Even after this was done an abscess formed upon the site of the opening into the chest, and discharged a quantity of pus. A smaller amount was once subsequently evacuated in a similar manner. The discharge was always purulent, and at the time of the primary operation and at various subsequent periods was horribly offensive. Exam-

ination two years after the operation discovered that vesicular respiration upon the affected side had been fully restored, and there was absolutely no discoverable pulmonary symptom by which the existence of any previous disease of the chest could be detected. It would seem that this case under the present mode of treatment would have afforded a result equally brilliant with those detailed by Dr. Cabot, as family history and previous health had both been unexceptionable in this patient, and perfect recovery was at length obtained notwithstanding the temporary occurrence of unfavorable symptoms depending probably upon absorption of septic matters from so extensive a surface of putrid suppuration.

Dr. GEORGE B. SHATTUCK concurred in the opinions expressed by Dr. Cabot and Dr. Richardson regarding the unfavorable prognosis attending the opening of the chest in cases of incipient phthisis. His observations upon patients in the City Hospital as well as upon those in private practice point conclusively to an unfavorable result from the operation in this class of cases. Such a personal or family history is of almost fatal importance in relation to a permanent opening in the chest wall.

Dr. CABOT called attention to the great rapidity with which the lung expanded after the dressing described in this paper, sometimes a few hours being sufficient for a full return of the pulmonary structures to their normal position in the affected side. Case XI. of the list reported in this essay presented a very striking example of this. In this patient the apex of the heart was found beneath the right nipple, whither it had been forced by the large purulent effusion within the left pleural cavity. In *eighteen hours* the heart had resumed its normal position, and the apex beat was found beneath the left nipple in its usual place. Thus in this short time the whole heart had moved bodily to a very considerable extent, the apex traveling in this time the entire distance from the right nipple to the left nipple without detriment to its organic function or to the system at large. At the same time respiration had returned to the affected side and was heard at the very bottom of the chest.

Dr. LYMAN observed that the shortness of the time for complete recovery was certainly very remarkable, the time of convalescence usually having been very long.

Adjourned at 9.30 P. M.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. SUCKINGHAM, M. D., SECRETARY.

JUNE 11, 1883. DR. CHARLES D. HOMANS presided. DR. MINOT reported the following cases:—

OBSCURER CASE OF ASCITES AND ANASARCA.

CASE I. The patient, a man fifty years old, entered Massachusetts General Hospital in November, 1882. His family history was good, but he had been a hard drinker for many years. He stated that he had had syphilis, but there were no symptoms of that disease, and the account was very obscure. He had also had palpitation and slight dyspnoea for many years. During the five months preceding his entrance he had progressive enlargement of the belly and swelling of the legs. The abdomen was much distended

¹ London Medical Record, March 15, 1883.

and fluctuating; the patient suffered from dyspnoea, and could not lie down; there was great oedema of the lower extremities and of the scrotum. The urine was high colored, acid, density 1018, contained a trace of albumen and a few hyaline and finely granular casts. He was tapped twice, seventeen and a half pints being withdrawn from the abdomen the first time, and eight pints three weeks afterwards, and he left the hospital. Five weeks afterwards (January 21st) he entered again with similar symptoms, and he began to fail steadily. The pulse became rapid, feeble, and intermittent, and the dyspnoea was at times very great. There was no cardiac murmur, and the impulse was not feeble. He had an inguinal hernia, which in the dropsical condition of the skin could not be kept up by any apparatus. It was necessary to tap him repeatedly. It was thought he could not live long. May 3d six drachms of Epsom salt were given in saturated solution, which acted freely, affording some relief, and it was repeated every few days. May 16th fifteen minims of tincture of digitalis were ordered in addition; copious diuresis at once set in, and by June 1st all traces of the ascites and oedema had disappeared; the heart's action, meanwhile, became regular and full, averaging eighty in the minute, and only intermitting occasionally. The liver was felt to be of the normal size, and no increased cardiac dullness was found. The patient was discharged to-day, well.

The diagnosis on the patient's entrance was cirrhosis of the liver, but Dr. Minot thought that must be abandoned. In the absence of distinctive signs of disease of the liver, heart, or kidneys sufficient to cause the long-continued and excessive dropsy, he was unable to give any plausible conjecture as to the nature of the disease.

PARALYSIS OF LOWER EXTREMITIES FROM LEAD;
RAPID RECOVERY UNDER IODIDE OF POTASSIUM.

CASE II. A woman, twenty-eight years old, entered the hospital April 25th. She had been married two years; never pregnant. She said she had contracted syphilis at the age of fifteen, having had sores on the vulva, some sore throat, night-pains in the legs, and loss of hair; but no eruption. Nine days before entrance she suddenly felt severe pain in the left knee, which was followed by numbness of the limb and inability to move it. Five days later there were prickly feelings in the right foot, and in the fingers. There were no appearances that could be ascribed to syphilis. The patient was thin and looked feeble. There was very little movement of the left leg. The plantar reflex was less good than in the other leg; sensation was about equal in the two. There was no difference in reaction to the faradaic current in the two legs, but in the left arm the response was more feeble on the radial side. The patient could not stand. No patellar reflex could be obtained in either limb on carefully testing. There was no ankle clonus. An indistinct blue line was observed on the gums, but no history of colic, and no wrist drop. The patient had no knowledge of being poisoned by lead in any way; but the urine was found on analysis to contain a considerable amount of lead. The pupils were normal, and an ophthalmoscopic examination of the eye showed no disease. She was ordered ten grains of the iodide of potassium three times daily, which was gradually raised to twenty-five grains three times daily. She soon began to improve, and on May 14th she could walk across the room

slowly without support; on the 21st she walked down stairs and in the garden. On the 26th she was discharged, well. There was a very slight patella reflex in the left leg, but none in the right. June 5th she returned for inspection, in good health, with good patella reflex in both legs.

DR. MINOT said that if he had not seen several cases of paralysis from lead which improved as rapidly as this under the iodide he might have considered this to have been a manifestation of constitutional syphilis. But the length of the interval between the last syphilitic symptoms and the present attack (twelve years), the absence of any such now, the presence of the lead line (though doubtful), and the discovery of the lead in the urine, all pointed to poisoning by that metal, and such cases were sometimes mistaken for other nervous diseases, especially progressive muscular atrophy.

DR. FIFIELD said that in the absence of a very positive lead line on the gum and of other symptoms he thought it going far off for a diagnosis to accept lead poisoning, neglecting syphilis, which was to him much more evident. Syphilitic paraplegia does not of necessity depend on gummy tumor and pressure on the cord. We may get nervous syphilitic symptoms as dilated arteries, and as deafness from affection of the auditory nerve, which are not known to be due to gummy tumor.

DR. MINOT, in reply to Dr. Fifield, said that in the first case there was no fever.

DR. FIFIELD spoke of the uncertainty of diuretics, and also of dysentery as a cause of ascites not often mentioned, but sometimes occurring, and he reported a case in which both ascites and hiccough were results, ascites making its appearance as dysentery was getting well.

DR. ABBOT asked if we could now be sure that the first case was not one of cirrhosis. It is well known that these cases may be tapped and refilled many times, and then go some time. He has known a case to go two years under such circumstances.

DR. MINOT stated that there was no decrease in the size of the liver.

DR. ABBOT also spoke of the uncertainty in the use of diuretics. He had known great ascites and anasarca in Bright's disease to disappear without the use of any drug. The patient had no physician until later in the disease.

DR. FIFIELD said that such good effects of iodide of potassium in lead paralysis are surprising. Treatment has vibrated between purgatives and the iodide. The speaker thought that one gets better effects from a combination of bromide of potassium with purgatives than from the iodide alone.

DR. WHITE said that so far as one can judge from the result of treatment, always a doubtful way of forming an opinion, he should think with Dr. Fifield that this case was one of syphilis.

DR. MINOT said that he had seen several cases of paralysis, many of which he had reported to this Society, in which iodide of potassium had had a good effect.

DR. WEBBER said that he had had many cases of lead poisoning in which the elimination of lead was increased by the use of iodide of potassium. He has seen cases in which lead appeared in the urine for the first time during the administration of the iodide, and stopped when the drug was stopped, to reappear when it was resumed. This has happened over and over again,

and he looked on it as proof. He had seen the gum line and the paralysis disappear during its use. He had been in some cases obliged to stop or diminish the iodide because of its producing lead colic, coming down to even a half grain or two grains. This last is not a symptom met with where the patient is merely intolerant of iodide of potassium. The speaker was doubtful if there is anything gained by the use of larger doses of the iodide than five or ten grains, but he has not tried. He mentioned a case in which there was double wrist drop with atrophy of the extensors leading to concavity in place of the roundness of the arm, and with a heavy lead line on the gum. The patient took ten grains of the iodide, getting some return of motion in five or six months, an almost complete disappearance of the lead line in eight months, and ability to do a good day's work in two years.

DR. GEORGE W. GAY read a paper on

THE MANAGEMENT OF PATIENTS DURING CAPITAL OPERATIONS.¹

DR. HODGES expressed his agreement with the reader. The duration and degree of etherization are of an importance which is apt to be overlooked, particularly by the young men who administer anæsthetics in our hospitals. Without the cognizance of the operator patients are often more deeply narcotized than is either necessary or advantageous by lavish use and crowding of the ether. Expedition, or, at least, the avoidance of unnecessary delay, in the actual performance of an operation, is also of much consequence. Demonstration, clinical remarks, consultation, the examination of interesting points by others than the operator are not infrequently detrimental, even though the patient's insensibility tempts such indulgences. That the element of time taken in operating is a matter of no moment is not, perhaps, so generally believed now as it was in the earlier days of anæsthetics. Even though a patient is wholly unconscious of pain, the shock of an operation, if its nature or the subject's condition occasions any, is rallied from in direct proportion to the duration of the procedure, and to the greater or less profundity of the etherization; and this is especially true of operations performed upon children.

DR. WARREN thought the reader had made some very good points. He thought it a question if the profoundness of etherization is not at times carried too far. He believed he had seen sinking beginning under a load of ether, and going on to end in death. By this he did not mean that there is any specific danger attaching to ether, but that it is one of the elements of an operation, and is to be considered. Movement is a danger to a feeble system. He had seen a patient go into collapse after being placed on the table, and die without being etherized or any operation taking place. He had in one case operated in the ward rather than carry a patient to the operating room, the reason being that the pulse became poor on starting. This patient recovered. Patients are apt to lose heat in the moving about before operation. All these are factors to be considered. Rapidity has been eliminated by the use of anæsthesia and still more by the use of the Lister dressing. This ought to be avoided. In the speaker's opinion there was a tendency to operate too early in bad cases. The pulse often improves in six or eight hours.

DR. FIFIELD, while agreeing in the main with the

¹ Reserved for publication.

previous speakers as to the value of speed, warmth, and little movement, said that he was at a loss to understand how the administration of ether can be a factor in causing an after state of death. It had always seemed to him an admirable stimulant. We can sometimes by its use put off death for minutes and hours. The stimulating effect of the subcutaneous syringe full of strong ether is a recognized fact.

TREPHINING THE RIBS.

DR. FIFIELD spoke of this operation, of which he had learned at the meeting of the American Surgical Society at Cincinnati, where it was brought up by Dr. Richardson, of New Orleans. It was first done there by Dr. Stone, of New Orleans, and is now the operation in that city. It is rapid and certain, and avoids the difficulty that annoys the operator in resection of the rib, of holding the bone steady while he is sawing through the second cut.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

CHARLES H. WILLIAMS, M. D., SECRETARY.

TREATMENT OF DOUBLE PNEUMONIA BY INHALATION OF OXYGEN.

MAY 7, 1883. DR. H. I. BOWDITCH mentioned a case of an old lady with double pneumonia, where both lungs were considerably hepatized, causing great suffering and difficulty of breathing. The trial was made of inhalations of oxygen, with the result of reducing the number of respirations, making them easier, and of changing the livid appearance of the face to a more natural color. The inhalations were continued at intervals for five days, during which time nine of the ordinary iron cylinders of the gas were used. At first it seemed as if the disease might go on to its natural resolution and recovery, but on the fifth day a collapse occurred from which the patient could not rally.

DR. EDES said that some years ago he had treated a child with capillary bronchitis with inhalations of oxygen; the pulse fell and respirations decreased, but the progress of the disease was not affected, and it resulted fatally. He also referred to some cases published by Dr. Smith, of New York, who had used oxygen to some extent in lung cases.

DR. J. S. MIXTER read a paper on

THE USE OF FUSIBLE METAL IN MAKING INJECTIONS FOR CORROSION ANATOMICAL PREPARATIONS.

The methods used by Hyrtl for corrosion preparations do not answer well in our climate as they are apt to melt in our hot summer weather. Henle used metal for casts of the ear, and Sands for those of the urethra, but no use seems to have been made of such metal for the finer injections of the blood-vessels. The compound used is known as Wood's metal, and consists of bismuth, seven parts; lead, four; tin, two; and cadmium, one. This will melt at a temperature of from 140° F. to 160° F. It should be melted under water which has been previously boiled in order to prevent the rapid oxidization which takes place when it is heated in the air. After having heated the organ to be injected to 140° F. the metal is forced in by means of a syringe, and the part left to cool for some time, for

when near the melting point it becomes quite brittle, but when cooler it can be handled quite safely. After having injected and cooled the organ it is immersed in a warm concentrated solution of caustic potash for some two hours, when the tissues become softened, and can be washed away with cold water.

Very beautiful preparations were shown of injections of the vein and artery of a human kidney, of the foetal circulation of a human child at birth injected through the umbilical cord, also preparations of the lungs of a sheep and a cat injected through the trachea, and specimens from the liver and kidney of animals. Dr. Mixer had also made some injections of bone by placing the specimen, immersed in the liquid metal, under the bell of an air-pump; the air was then exhausted, withdrawing the air also from the interior of the bone; on readmitting the air to the bell the metal was forced into the finer bony openings, and a cast was thus obtained. It was often necessary to soak the bone for a week in the strong potash solution or even to use strong sulphuric acid.

DR. WOOD suggested the use of hydrochloric acid before injecting so as to remove the phosphatic portion of the bone, but it was thought by the reader that this might affect the finer membranes lining the bony canals, and interfere with the accuracy of the injection.

DR. HARRINGTON read a paper on

A NEW AND SIMPLE METHOD OF DETERMINING THE PERCENTAGE OF FAT IN MILK.

Several kinds of apparatus were shown, and a brief description was given of the methods commonly used, including Marchand's lactobutrymometer, Chevallier's cremometer, Soxhlet's new areometric process, and the quartz sand method. The attention of the Society was then called to the Feser lactoscope, a small instrument designed to determine rapidly the percentage of fat in milk, and on account of its great simplicity peculiarly adapted for domestic use. The principle of the instrument depends on the fact that the more fat there is in the milk the more opaque the fluid becomes. The instrument consists of a cylinder of glass, into the end of which is fitted a stopper carrying a small rod of white glass on which some black lines are marked. A small quantity of milk (four c. c.) is now poured into the upper end of the cylinder, and water is added in small quantities until the black lines can be seen on the glass rod; the contents of the cylinder are shaken from time to time as the water is added in order to mix it thoroughly with the milk, and when the black lines can be seen the percentage of fat can be read off at once from a scale on the side of the cylinder at the level of the diluted milk. Dr. Harrington stated that he had made a number of comparative tests between this instrument and other methods, and had found that it gave very satisfactory results.

In reply to Dr. Wood the reader said that good milk should have from two and one half to three per cent. of fat. Some analyses of human milk have been recently published in which the results of different observers have been tabulated. From this it appears that the average percentage of fat in human milk is about two and one half per cent., but the analyses vary so much that the results of any one man can hardly be taken as reliable.

DR. HAVEN said that he had used the Feser's instrument at the West End Nursery with very satisfactory results. It shows a very great variation between dif-

ferent cans of milk as supplied by the same milkman, the variation being from two and one fourth to four and one half per cent. of fat, and he had found it much better to have the milkman mix the contents of all the cans together before bringing it to the city rather than to try to get the supply from any one cow, for in this way the percentage of fat would be the same in the milk supplied to all the children, and much more accurate observations could be made on the comparative results of feeding than where the variation between the milk for the different children was so great as under the plan of separate cans. Where the percentage is reduced below the normal it is likely to be a source of inanition, but where the fat is unduly increased it gives rise to intestinal trouble on account of a lack of a proper amount of pancreatic juice to properly digest it. It was not thought that the coloring matters used to doctor milk would interfere with the use of this instrument, for although they might affect the color of the milk they would not change its opacity to any very great extent.

Recent Literature.

A Treatise on Insanity in its Medical Relations. By WILLIAM A. HAMMOND, M. D. Published by D. Appleton & Co.

The most valuable portion of this book is the first third, in which the author considers the general principles of the physiology and pathology of the human mind, instinct, and sleep. His estimate of the importance of psychical peculiarities, which non-experts are apt to regard lightly, is none too high, as a correct appreciation and understanding of these minor morbid changes is likely to open the most hopeful field to physicians treating mental diseases. For such appreciation should lead not only to hygienic and medical care, but to an intelligent adaptation of education and occupation to the individual, so that they shall assist in establishing and preserving mental integrity, where instability has been inherited or acquired, instead of taking away the small chance left, as they are likely to do when not so adapted. Mental peculiarities are now about the only evidences of weakness that fail to receive sympathy from the strong, and their unfortunate possessor is apt to be made the butt of ridicule and goaded to educational training or occupation, for him most ill-advised, until the brain completely gives way, and he is branded lunatic, and despaired of. It is to be regretted that the author, though making these chapters of his book curious and interesting by the recital of cases observed by himself and quoted, fails to offer many practical suggestions in the way of treatment.

In the remainder of the book, devoted to the consideration of insanity proper, the clinical description is graphic and usually good. We have become accustomed to expect a new classification from every writer upon insanity, and, as all classifications must be unsatisfactory with our present knowledge, it is hardly worth while to criticise severely any particular one. Perhaps the chief objection to this one rests in the fact that it is another; though as one variety, he describes "perceptual insanities," "which constitute the primary form of mental aberration, and of themselves are not of such a character as to lessen the responsibility of the individual or to warrant any interference with

his rights. They consist entirely of false perceptions; and if the intellect should be for a moment deceived, the error is immediately corrected." The author's own definition would hardly include this as a form of insanity, and it is rather difficult to understand how illusions or hallucinations of the senses, whether centric or peripheral in origin, can be considered evidences of insanity when they are recognized as unreal, and do not become a basis of action.

In the closing chapter, on treatment, a strong dislike to hospitals for the insane, particularly those in this country, is manifested, and the observations concerning them here, as elsewhere in the volume, are often decidedly lacking in discrimination and candor. Thus, when he says "the number of acts of violence committed in public asylums during the last five years is manifold greater than that perpetrated by all the lunatics whose condition has been recognized, and who have been under the care of their friends or in some private institution for the insane," he simply makes a guess, which is probably the reverse of the truth, and which, if correct, would have no force as an argument, because in this country and abroad a very small proportion of patients who are decidedly dangerous to themselves or others are under the care of their friends or in private institutions, as the proprietors of these institutions, finding the risks and annoyances connected with the treatment of such cases greater than the advantages, usually refuse them admission, while relatives do not consider them suitable to home treatment. The comparison would thus be between a class composed almost entirely of what are often termed harmless lunatics and a class including nearly all the dangerous ones that are under treatment at all.

It also seems to us that the doctor isolates and groups the undesirable features connected with hospital treatment in a way which gives a wrong impression, and he leaves it to be inferred that these troubles can be avoided by keeping the patient out of a hospital, whereas most deplorable results of the kind mentioned often follow the home care of the insane when made without systematic expert selection and supervision. The expense of this supervision, medical and other, makes it unattainable to more than nine tenths of the insane; and the young practitioner will find little of the practical instruction in this work which will enable him to meet intelligently the emergencies that are likely to arise in the case of acute insanity which the author has advised him to keep at home.

Medical Essays. 1842-1882. By OLIVER WENDELL HOLMES. Boston: Houghton, Mifflin & Company; The Riverside Press, Cambridge. 1883.

We welcome with pleasure these old friends in their new garb. In turning the pages that contain, among other papers, these addresses of Dr. Holmes, to which students and practitioners have so eagerly listened, we realize that each address must have formed a sort of epoch in some life, as it marked the entrance upon medical study or the attainment of that period when the student was deemed sufficiently advanced to pursue his studies in his own field without the interference of professors and teachers. It is with peculiar pleasure that we turn back to that lecture which served, in that graceful manner now abandoned, as an introduction to our own entrance upon professional labor. It

is almost humiliating to see how many of our pet ideas and maxims are contained in that single address. Can it be that the ideas of that opening lecture so impressed us that what we have fondly called our *ego* is after all but the echo of Dr. Holmes?

It was certainly good fortune to fall in that early day under the influence of so wise and genial a teacher.

These essays have helped all of us who came under their influence to appreciate the fallibility of human testimony and to deliver us from the "dead hand of medical tradition."

We remember well enough that not all the author's words were received with smiles from all quarters, as he told us of some of our own follies and consigned the majority of drugs to the fishes.

We trust the intelligent young gentlemen of the present day who, passing an entrance examination, need no other welcome to their studies, and who go their way into the world without a formal "God-speed," will add to their many acquirements a knowledge of the good things their elder brothers have learned from Dr. Holmes.

Brain-Rest. By J. LEONARD CORNING, M. D. New York: G. P. Putnam's Sons. 1883. 103 pages.

Perhaps the danger of overtaxing the brain cannot be too strongly insisted upon, and it may be well to publish many brochures thereon. This little treatise is scarcely deserving of book form; nearly all that is said in it has been frequently repeated. Some of the statements might be questioned, but on the whole there is much that is good. The chief object of the author seems to be to introduce a new method of treatment,—the mechanical regulation of the cerebral circulation by compressing the carotids. The author has invented instruments by means of which pressure upon the carotids can be maintained for any time desired. It might be questioned whether other parts would not be also affected. Never having tried his plan we do not feel justified in expressing a positive opinion, but the usefulness of this method seems to us very doubtful.

Insanity: Its Causes and Prevention. By HENRY PUTNAM STEARNS, M. D. Published by G. P. Putnam's Sons, New York.

This book presents a sociological study of the causation and prevention of insanity, which cannot fail to prove of much value to the general practitioner, as well as to the intelligent layman and educator to whom it is chiefly addressed.

In the preliminary chapter the author recites some of the improvements which have taken place in hospitals for the insane of late years, and claims that they now deserve and receive much more public confidence than formerly. He also makes the statement, with less qualification than seems to us desirable, that the "atmosphere of home and the care of friends are unfavorable conditions" in the treatment of the insane.

In considering the question of increase of insanity, he has very properly made no attempt to gain anything from the unreliable records of past years in the United States, but has taken the ratio of persons recognized to be insane to the whole population in Great

Britain for two decades following 1859, and finds it an almost continually increasing one. In England in 1859 one person in 535 was insane, and in 1878 one in 362. In Scotland in 1860 one person in 487 was insane, and in 1879 one in 392. The author concludes that these statistics show, when due allowance has been made for inaccuracies, that there is a large increase of insanity both absolutely and relatively to the population in both England and Scotland, and thinks that the reports of the recent United States census point to the same conclusion for this country.

The belief expressed that emigrants present a high average of mental health cannot well be proved erroneously by statistics, but we think the observation of those familiar with the emigrants landing in Boston in recent years would indicate otherwise; and the explanation offered that the special prevalence of mental disease among unskilled laborers is largely due to the fact that they have never been subjected to any systematic mental training seems less probable than that it is due to inherent mental weakness which predisposes its victims to insanity as well as renders them incapable of rising above the grade of common laborers. The chapters on the insane diathesis and on education are excellent, and one is inclined to regret that several chapters, containing much advice about drinking, smoking, marrying, and morals, which is all admirable, but either not new or of a kind not likely to be heeded, have increased the size of the volume so that these especially valuable portions may not have as wide a circulation among educators as their merit makes desirable.

Oliver Wendell Holmes, Poet, Litterateur, Scientist.

By WILLIAM SLOANE KENNEDY, author of a *Life of Henry Wadsworth Longfellow*, etc. Boston: S. E. Cassino and Company. 1883. 356 pages.

This is an interesting book, as any book must be that deals with so interesting a subject. It gives the main points in the life of its distinguished subject. To fill out its pages some extraneous matter is introduced. It contains two things of real value,—a bibliography compiled with great care, including contributions to periodical literature, and a collection of brilliant paragraphs and *mots* gathered from fugitive publications.

Chromatoptometrisk Tabel, Chromatoptometrical Table.

Ved DR. OLE B. BULL. Christiania: 1882. New York: Wm. Wood & Co.

Dr. Bull's table is intended to furnish a means for determining the acuteness of the color sense much in the same way as an estimation of the acuteness of vision is made by the use of Snellen's types, and, as in the latter case, the result is to be stated in a fractional form. In the color table, however, the size of the test object and its distance from the patient remains always the same, the determination of the amount of the color sense being made solely from the varying degree of intensity of the colors. Only the principal colors, blue, green, yellow, and red, are employed. Squares of these colors and of gray are arranged on a black background in ten rows, the squares in each row having the same degree of luminosity. In the first row the tints are so faint as to be just distinguishable by a

healthy eye at a distance of one meter, in the other rows they are progressively more intense.

The table has evidently been constructed with great care; it does not seem well adapted to take the place of the worsted tests for physiological color-blindness, nor does this appear to be the object of its author; of how great advantage it may prove to be for estimating the progress or improvement of pathological color defects can only be decided by extended experiment.

Lectures on Cataract: its Causes, Varieties, and Treatment, being Six Lectures delivered at the Westminster Hospital. By GEORGE COWELL, F. R. C. S., etc., etc. London: Macmillan & Co. 1883. 126 pages.

A series of six lectures delivered to the students of the Westminster Hospital, and published at the request of some of the author's old pupils. The subject of the lectures is shown by the title, and they are preceded by an account of the anatomy of the lens taken from Quain's Anatomy. The greater part of the book, four lectures, is given to the discussion of the various operative methods for treatment of cataract. The lectures are rather elementary in character, and contain little of importance not to be found in the better text-books on diseases of the eye.

Type and paper are excellent.

Alcoholic Inebriety from a Medical Stand-point. With Cases from Clinical Records. By JOSEPH PARRISH, M. D. Philadelphia: Published by P. Blakiston, Son & Co.

This book pleads strongly for the recognition of inebriety as a disease in a very large proportion of cases, and is evidently addressed chiefly to lay readers. The style is pleasant, though somewhat diffuse and florid, and many interesting cases are cited, which would, however, have greater interest if the histories were more complete from a medical stand-point.

— It is said that a prominent manufacturer of pepsine has applied to good advantage the well-known physiological fact that the emotions awakened by the contemplation of appetizing food not only cause the saliva to flow—or make the “mouth water”—but they also stimulate a secretion of gastric juice. Taking advantage of this fact, fasting pigs are turned into a pen where a trough filled with hot mush is covered with a wire screen to prevent them from eating it, and thus absorbing the pepsine contained in their peptic glands. They are then in due time killed, and the yield of pepsine is said to be greater than when no such physiological method of procedure is resorted to.

— It was an unfortunate metaphor, that of the London doctor, who, having been sent for by a lady in Chelsea, remarked, on her apologizing for asking him to come such a distance, “Don't speak of it. I happen to have another patient in the neighborhood, and can thus kill two birds with one stone.”

Medical and Surgical Journal.

THURSDAY, AUGUST 9, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

ANNUAL REPORT OF THE BOSTON BOARD OF HEALTH FOR THE YEAR 1882-1883.

THIS eleventh annual report of the Board of Health of the City of Boston states the sanitary condition of the city during the past year to have been "altogether satisfactory," by which we do not infer that further ameliorations are despaired of, but that as much progress has been made in preventing or diminishing causes of sickness and death as could reasonably be expected in one year.

The death-rate is lower than for several years; there has been a considerable decrease in number of deaths from preventable causes; there has been no epidemic; the rate of infant mortality is below the average for the past ten years.

The population, estimated on the basis of assessed polls on males over twenty years of age compared with the past twenty-five years, is placed at 410,376, and the death-rate is 21.91 on this estimated population. The rate of the year 1881 was 22.67; that of 1880 23.52; and the average rate of the past eighteen years was 24.30.

The total number of deaths from zymotic diseases, notwithstanding the increase of population, has been less than during either of the two previous years, and the percentage to the total mortality is the lowest since 1874. In 1880 there were 2321 deaths from zymotics; in 1881 the number was 2423; in 1882 it was 2276. This is a most gratifying exhibit, and speaks well for the comparative sanitary condition of the city. The most fatal of the zymotic diseases is diphtheria, which the Board has made every effort to combat. Its decrease over the two previous years is most marked not only in the number of deaths, but in the percentage of actual deaths to the cases reported. In 1880 the number of deaths from this cause was 588; in 1881 the number was 601; and last year the number was reduced to 458.

There were but eight deaths from small-pox, and twenty-four reported cases, a result extremely creditable to the good judgment of the Board and to the efficiency of its measures, and the more striking when compared with the reports from other cities, New York reporting 259 deaths from this disease; Philadelphia 228; Chicago 1292; Cincinnati 1249; Baltimore 551; New Orleans 268; Pittsburg 300. The freedom of Boston from small-pox, moreover, exemplifies the advantage of giving a board of health ample powers when dealing with such an enemy. Isolation,

thorough vaccination, and careful fumigation of infected premises and clothing are the measures upon which reliance has been placed.

The decrease in the deaths of children under five years of age is considerable when the number of deaths of the past year is compared with the average number of the previous ten years, or with the years 1880 and 1881. In the former year the number of infant deaths was 3349, and in the latter 3314, while in the past year the number was 3151. The percentages of the seven years previous are reported as showing a steady and perceptible decrease.

The report contains some interesting items in regard to the so-called zymotic or infective diseases other than the small-pox. The diseases which the Board has classed as contagious and dangerous to the public health within the meaning of the statute law, and which physicians and householders have been required to report, are small-pox, diphtheria, scarlet, typhus, and typhoid fevers, and measles. Physicians were first required to report cases of scarlet fever in January, 1877, "and at the same time an order was passed forbidding children attending school from any family in which this disease existed. A circular of instructions was also issued and sent to each family where a case was reported. It was thought not to be advisable at that time to interfere beyond these measures with scarlet fever. The record then showed an average of 399 deaths yearly, for the previous ten years, from this disease.

"The number of deaths from scarlet fever each year, for the last ten years, is shown in the following table:—

1873.	1874.	1875.	1876.	1877.	1878.	1879.	1880.	1881.	1882.
474	269	534	458	104	68	149	33	35	75

"Reports of cases of diphtheria were called for in December, 1877, and a circular of instructions issued and used as in cases of scarlet fever.

"Soon after the Health Board had prohibited children attending school from families where scarlet fever existed the School Board prohibited the attendance of all children from houses where any infectious disease existed. It therefore became unnecessary for the former to make any further prohibition. Diphtheria has been endemic in the city for many years, has produced a large mortality, and is not generally regarded in the community as a very contagious disease. All cases of contagious disease and their location reported to the Health Board are given to the truant officers for the use of the School Board every day. The number of deaths from diphtheria for the last ten years is given in the following table:—

1873.	1874.	1875.	1876.	1877.	1878.	1879.	1880.	1881.	1882.
59	72	420	577	364	448	391	588	601	458

"Typhus fever has rarely occurred in Boston for many years. Reports of this disease were called for in 1877; since then seven cases have been reported in the city, and five in quarantine. Only two deaths have occurred from this disease; those were taken at the same time from the City Hospital to quarantine,

where both father and son died since the date of this report.

"Typhoid fever has prevailed, with some variation from year to year, during the last decade, diminishing gradually in the number of deaths until 1880, when the number began to increase again. The prevalence of the disease in the fall of 1881 caused the Board to call upon the physicians for reports of all cases occurring within the city. An investigation of about 250 cases was made with a view of ascertaining the prevailing cause of the disease; but this was followed with no satisfactory results, except the fact that a large number of the cases were in persons who had just returned from the country."

The number of deaths from typhoid fever in each year for the last decade is given in the following table:—

1878.	1874.	1875.	1876.	1877.	1878.	1879.	1880.	1881.	1882
243	202	227	145	156	120	119	154	207	212

The Board thinks if as effective measures could be taken for isolation and fumigation in the other infective diseases as in small-pox that a much more marked decrease would be observed in their prevalence; in fact, there has been an increase in the prevalence of some of these diseases. The most difficult infective diseases to be brought under the control of a board of health are those which are mildly infective and do not inspire the community with dread. The Boston Board thinks that what is wanted "is sufficient hospital room for the proper care and isolation of every case as soon as the Board of Health shall decide that it cannot be properly isolated at home, and that its condition will permit of removal to hospital without danger to the patient's health. There would be no hardship in thus removing the patient, but in very many instances it would be the means of saving life, and the city would be but doing what is imposed upon her by statute law."

Of the houses in which diphtheria occurred over seventy per cent. were found to be in a defective sanitary condition. A short report by Mr. Ernest W. Bowditch giving the results of an investigation into diphtheria in East Boston with a topographical chart is included in the general report of the Board, and we extract the following: "The data offered are certainly insufficient to draw general conclusions from, but the indications appear to be that when the schools are not in session the disease is not so prevalent; moreover, almost immediately upon the beginning of the long summer vacation there has been, for several years, a very decided drop in the number of cases reported, and the low number appears to continue until the autumn term begins." The schools must undoubtedly be held responsible for much of the spread of all the infective diseases.

In referring to sewerage the report contents itself with expressing the hope that the great system of intercepting sewers now under way will be prosecuted with all possible dispatch, and a confidence that it will bring relief from the present annoyances.

As to the water supply the report says:—

"The new Water Board appear to believe that the citizens who complain of the water are not unreasonable in their complaints, and that it is possible, by diligence and well-directed energy, to improve the condition of our drinking water. This is a long step in advance.

"The two principal things to do, as it seems to us, is to prevent the pollution of the water, and to properly construct and prepare the basins to hold it."

The danger to Boston of an epidemic of typhoid fever in Natick or Ashland is very properly dwelt on.

Want of space precludes our dwelling upon a number of interesting subjects suggested by this report.

BOSTON CITY HOSPITAL; NINETEENTH ANNUAL REPORT.

THE report of this institution for the current year is at hand. The total number of patients treated in the hospital was a little in excess of that for the previous year or two, and the expense also shows a slight increase, being at an average of \$9.80 per week for all the patients treated. While 4702 individuals were received into the house, some 12,000 were treated in the various out-patient departments, to which they made on the average some three and one third visits each. The average period during which the inside patients remained under treatment was 22.20 days each.

Certain facts taken from this report serve to show the function which this hospital fills among our local charities. Of the whole number of patients admitted 666 were cases of accidental injury, 149, being more than thirty-one per cent. of the whole number of deaths, died within forty-eight hours after admission. The general mortality was exactly ten per cent., which is practically what it has been for several years. The nativity of the patients is largely foreign, 1542 having been born in Ireland, against 865 born in Boston, and 301 in the rest of Massachusetts.

The trustees call attention to the need of better accommodation for cases of contagious disease, the beds devoted to that purpose being no more numerous now than they were at the inauguration of the hospital, when the total yearly admissions were not a quarter of what they now are. The reception of various kinds of contagious diseases, and the necessity of isolating the one from the other, makes it impossible to use nearly all the beds in the contagious wards. Thus it often happens that, in isolating rooms with four beds each, eight patients of both sexes may occupy the rooms which could be utilized for thirty-two patients, provided no classification was necessary.

The trustees renew their plea for additional accommodations for the nurses of the training-school, both for the sake of the nurses themselves and in order that the rooms now occupied by them may be made available for general hospital purposes. The city council has failed thus far to make any appropriation for the building asked for.

Additional space is also requested for the various

out-patient services, now numbering eight, which are cramped up in rooms originally designed for only three services.

The document contains a full tabulated list of all the cases of disease treated during the year, interesting as showing the relative proportion of the different maladies that present themselves in a large metropolitan hospital. The staff and officers of the institution are to be congratulated on the completion of a year of faithful and valuable work.

MEDICAL NOTES.

— We learn that Dr. John S. Billings has declined the offer of the professorship of Hygiene in the Johns Hopkins University, recently made him. The reasons which he assigns for doing so are that he cannot give up his position as surgeon in the army and superintendent of the National Medical Library, which he would be obliged to do if he accepted the position in question. He has consented, however, to deliver a course of lectures on Hygiene in the institution during the coming winter.

— Filippo Pacini, doubtless the most eminent physician in Italy, has recently died at the age of seventy-one. He filled successively a number of professorships of Descriptive and Topographical Anatomy, as well as that of Artistic Anatomy in the Academy of Fine Arts at Florence. Histology, however, was the field in which he won his highest fame. He was a voluminous writer on all sorts of medical topics. Among his productions were *Observations and Analytical Experiments on the Movements of the Heart and the Sounds which Proceed from Them*, Pisa, 1837; *On the Inertia of the Diaphragm in Defecation and Parturition and on its Action in Vomiting*, Pisa, 1837; *New Microscopic Researches on the Internal Texture of the Retina*, Bologna, 1845; afterwards reprinted at Freiburg in a German translation in 1847; *On the Electric Organ of the Silurus of the Nile*, Bologna, 1846; *On the Mechanism of the Intercoastal Muscles in Respiration*, Pisa, 1846; *New Microscopic Researches on the Texture of the Bones and Teeth*, Florence, 1851; *On the Electric Organ of the Torpillus, Gymnotus, and other Fishes, on the Electro-Motor Conditions of their Electric Organs and their Respective Comparison with the Thermo-electric and with the Voltaic Pile*, Geneva, 1853; *Microscopic Observations and Pathological Deductions on Asiatic Cholera*, Florence, 1854, republished in a French translation at Brussels in the following year; *On the Nature of Asiatic Cholera and its Comparison with European Cholera, and with other Intestinal Discharges*, Florence, 1866, reprinted in an English translation in 1868; *New Method of Practicing Artificial Respiration on the Asphyxiated*, 1867, reprinted in French and Spanish translations in the years 1871 and 1877 respectively; *On the Osmotic Phenomena and the Functions of Absorption*, 1873; *On the Extra-vascular Part of the Circulation of the Blood*, 1875; *On the Duration of the Possibility of Resuscita-*

tion from Apparent Death in Cholera, with Some Cases Illustrative of the Author's Method of Artificial Respiration, 1877.

— Glanders has broken out in the stables of the Newark and South Orange Horse-Car Line, N. J., and the mayor of Newark has issued an order forbidding the driving of any horses from the infected stables into the city. Four of the animals suffering from the disease were shot on the 2d of August. A horse affected with glanders has also been shot at Paterson, N. J., by order of the health authorities.

— The Madrid *Estafette* states that a Spanish gentleman, Señor Lucas Nequeiras Saez, who emigrated from his native land to America seventy years ago, recently returned to Spain in a steamer of his own, and brought with him the whole of his family, which consists of no fewer than one hundred and ninety-seven souls, sons-in-law and daughters-in-law not included. Señor Saez has been three times married. His first wife had eleven children at seven births, his second had nineteen children at thirteen births, and his third had seven children at six births. The youngest of this family of thirty-seven is aged nineteen; the eldest, who is seventy, has seventeen children, of whom the first-born is forty-seven. Of Señor Saez's twenty-three sons, all of whom are living, thirteen are married, six are unmarried, and four are widowers; and of his surviving daughters nine are married. The granddaughters number thirty-four, and of these twenty-two are married, nine are unmarried, and three are widows; and of the forty-five grandsons twenty-three are married, seventeen are unmarried, and four are widowers. There are also forty-five great-granddaughters and thirty-nine great-grandsons, of whom three are married. Señor Saez has never tasted wine or any alcoholic liquor, and lives chiefly upon a vegetable diet, with but little salt. In spite of his ninety-three years, he is still hale and hearty, and makes a point of walking briskly for at least three hours every day.

— According to *New Remedies* there is a difference in therapeutic effect between jaborandi and its alkaloid. Jaborandi is both a sudorific and saliva-increasing drug; the alkaloid pilocarpine, however, appears to possess the last-named property in much greater proportion, a fact which has been noticed by many careful observers. Probably some of the other principles contained in jaborandi, perhaps *jaborine*, are more energetic in the other direction.

NEW YORK.

— On the 26th of July Dr. F. Langé, one of the visiting surgeons to Bellevue Hospital, performed the rare operation of ligating the common iliac artery, in the amphitheatre of the hospital, with the assistance of Drs. Charles McBurney, Samuel Lewengood, house surgeon, and others, and in the presence of a considerable number of physicians and surgeons. It was undertaken for a large aneurism of the external iliac, and at the end of a week there was a fair prospect of the patient's recovery.

— Some twenty cases of enteric fever, two of them fatal up to date, have occurred at Newburgh on the

Hudson within an area of half a block, the result of drinking the water of a well contaminated with sewage. In several families there have been as many as three cases, and in one instance, four. A short time ago the ordinary city water was temporarily unpalatable, and hence various wells and springs were resorted to. As far as known, all the cases of fever were caused by the water of the one well, which was without odor, clear, and pleasant to the taste.

— At a meeting of the new Aqueduct Commission, held August 8th, Mr. Hubert O. Thompson, Commissioner of Public Works, in accordance with the section of the law requiring his department to furnish plans for the work, submitted the details for an additional water supply to the city, which he said were the result of two and a half years of the best thought and labors of the Public Works Department, aided by the suggestions of the ablest hydraulic engineers of the country. The proposed aqueduct, extending from Quaker Bridge reservoir to the Central Park reservoir, would be $31\frac{8}{100}$ miles in length, which is only $\frac{1}{100}$ of a mile longer than an air line. Of this distance 128,956 feet would be in tunnel (for the most part in rock), 3350 feet in excavation, and 8005 feet on embankments. About eight culverts would be required between the Quaker Bridge dam and the Harlem River, and the latter would be crossed by a tunnel 2320 feet long. The width of the Manhattan valley is 4000 feet, and it is designed to cross it by iron siphons. The proposed aqueduct would be circular in form, twelve feet clear interior diameter, and would have a capacity of delivering about 250,000,000 gallons per day, this being the total constant supply which the Croton watershed can with absolute safety be relied upon to furnish at all times and seasons. The combined capacity of the two aqueducts would, therefore, be 350,000,000 gallons per day. It is believed that the new aqueduct can be made available at the end of three and a half years after the beginning of the work, and that the dam at Quaker Bridge can be completed in probably the same time, though it may possibly require five years. This new dam, if constructed, would probably be the most extensive structure of the kind in the world, and in raising the water in the Croton valley thirty-three feet above its present level would produce a reservoir with a capacity of 30,000,000,000 gallons above the level at which it would be drawn off by the aqueduct. The estimate of the entire cost of the dam, reservoir, and aqueduct is placed at \$14,460,940.

— The cases of contagious diseases reported during the week ending August 4th were as follows: typhus fever, five; typhoid fever, forty-nine; scarlet fever, thirty-five; cerebro-spinal meningitis, four; diphtheria, twenty-three; measles, fifty-two. Four of the cases of typhus fever were discovered in one tenement house on Water Street. Among the deaths reported during the week was that of Christina Manning, an unmarried woman, aged one hundred and two years. She was a native of Ireland, and came to America seventy years ago.

— Another case has been added to the increasing

number of deaths from accidental poisoning by carbolic acid. A lady residing on Columbia Heights, Brooklyn, arose from bed about 6.30 A. M. on the 6th of August, and, going to a closet, drank a wine glass full of a solution of carbolic acid (the strength of which is not stated) in mistake for some other medicine which she was in the habit of taking. At once discovering her mistake, she hurried to a neighboring drug-store, where an emetic was promptly given her. Medical aid was also immediately summoned, but she died in great agony at 8.30 A. M.

— On the 1st of August the number of inmates in some of the institutions under the charge of the Commissioners of Public Charities and Corrections was as follows:—

	Inma- August 1, 1883.	Treated during the Year.
Bellevue Hospital	550	10,200
Reception Hospital, Ninety-Ninth Street	15	642
Homoeopathic Hospital, Ward's Isl- and	380	5,221
Charity Hospital, Blackwell's Island	1,015	7,045
Infants' Hospital, Randall's Island	157	1,017
Children's Hospital, Randall's Island	264	877
Idiot Asylum, Randall's Island	208	287
Adult Hospital, Randall's Island	112	567
Branch of New York City Asylum for Insane, Randall's Island	126	185
New York City Asylum for Insane (Female), Blackwell's Island	1,610	1,904
New York City Asylum for Insane (Male), Ward's Island	1,846	2,080
Branch Lunatic Asylum, Hart's Isl- and	230	434

— Veterinary Inspector McLean, of Brooklyn, in a report to Health Commissioner Raymond, states that an inspection of the cow stables of Brooklyn confirms the reports of the existence to an alarming extent of contagious pleuro-pneumonia among the milch cows of that city. He reports that eight per cent. of the entire milk-producing stock of Brooklyn is affected with the disease, and that he finds no evidence that the recent action of the State Board of Health in ordering the slaughter of the diseased animals has in any way mitigated or curtailed its prevalence. He has inoculated a large number of cows as a preventive measure, and this, he believes, is the only method by which it can be stamped out.

— Dr. George H. Fox and several other New York physicians interested in diseases of the skin have recently returned from New Brunswick, where they have been making a careful study of the cases of leprosy in the Tracadia Lazaretto. These are now twenty-four in number, although five years ago there were thirty-six.

— A negress accompanied by her husband recently came into the Jefferson Market police court and complained to the justice presiding that she had been bewitched by two white men, who came to her house and sprinkled a mysterious powder about the premises, in consequence of which she suffered great pain and was tormented by snakes and vermin. She stated that she had previously been made to suffer in a similar way by a colored man with an "evil eye"; but that she had succeeded in procuring a "fet sh," which had effectually released her from his diabolical spells.

The fetish, however, had proved entirely unavailing in the case of her white tormentors. It proved on examination that the latter were nothing more or less than members of the disinfecting corps of the Board of Health.

Correspondence.

LETTER FROM LIVERPOOL.

THE BRITISH MEDICAL ASSOCIATION.

LIVERPOOL, August 4, 1883.

MR. EDITOR,—The British Medical Association is so well known in New England that a few rambling notes on the annual meeting, which has just been held in this city, may be acceptable to your readers.

The session opened on July 31st, with an attendance of about six hundred members, an attendance not larger, you will notice, than is usually present at the annual meetings of the Massachusetts Medical Society, although the membership of this Association exceeds ten thousand (10,000). The general meetings, as well as the meetings of the ten sections, were held in the Medical College building on Shaw Street, in which were also a post-office, telegraph and telephone offices, lunch room, waiting and writing rooms, besides the usual exhibits of surgical instruments and appliances, drugs, dressings, etc., etc. Bigelow's latest lithotrite and evacuator were noticeable; celluloid catheters and "Gamgee's tissue," which is simply absorbent cotton between layers of gauze, were about the only new features to me. The arrangements were in the hands of committees on reception, excursions, local entertainments, soirée, dinner, printing, museum, etc., and their duties were well carried out.

The general meeting on the second day was opened by Mr. Reginald Harrison, who gave a very interesting address touching the more modern improvements in the surgical treatment of diseases of the urinary organs. The work done by Bigelow, Otis, Gouley, and other American surgeons was fully acknowledged and cordially applauded. Mr. Harrison considers the Bigelow operation a great step in advance in the removal of vesical calculus, but does not think it adapted to all cases. Although he did not specify the class of cases not thought suitable for this method, it is fair to presume that he would include cases of stone in young children, and also very large and hard calculi in which the small calibre of the urethra in the one case, and the long time required for crushing and evacuating the fragments in the other, might be considered good reasons for resorting to some other method. So far as I know neither of these points have yet been decided by the crucial test of experience. Mulberry calculi, an inch or a little over in diameter, have been successfully removed by this method. Larger calculi of this species are rare. There can be little doubt in the minds of practical surgeons, who have had any experience with Bigelow's method, that it is the best one yet discovered for the removal of all ordinary vesical calculi in the adult.

In one instance Mr. Harrison cut down upon, and removed a large portion of a cancerous prostate with very satisfactory results. At the end of eight months the man was comfortable, and, although there was a

fistulous opening remaining, yet he was much benefited by the operation. Mr. Bickersteth and Dr. Ashurst, of Philadelphia, have performed the operation with fair results. Mr. Harrison is a firm believer in the personal use of the soft rubber catheter of Mr. Jonathan Hutchinson, in the early stage of prostatic enlargement, even before there is really any obstruction. To establish a free evacuation of urine in advanced cases of prostatic obstruction he advocates the operation of puncturing the bladder through the membranous urethra and prostate, and fastening in a tube or canula. Nothing indicates the advance in the treatment of stricture of the urethra more clearly than the comparative infrequency of the old-time, impermeable strictures, which are never seen at the present day by many surgeons of extensive experience.

The meeting of the Surgical Section was opened by Mr. Rushton Parker, who read a paper on Intestinal Obstruction, which gave rise to quite an interesting debate. Dr. Edward Waters reported a case of a large abdominal tumor accompanied by constipation, pain, constitutional disturbances, finally ending in collapse. Sir Spencer Wells opened the abdominal cavity, found the cæcum, ascending and transverse colon enormously distended with feces, made an artificial anus, and the patient recovered. In commenting on this case Mr. Wells said that it was very obscure throughout, and to this day he does not know the nature of the obstruction.

Mr. Wells has opened the abdomen thirty-four times for intestinal obstruction. The results have been so satisfactory, notwithstanding a large mortality, that he has no hesitation in recommending the operation. His favorite place for opening the bowel is in the right loin, well back toward the spine, between the crest of the ileum and last rib. He claims that the gut is more easily reached in that side, and that there is less danger of wounding the peritoneum, although he does not think the risk to the patient is much increased by that mishap, relating a case in which he accidentally opened the peritoneal cavity, but the patient recovered. Mr. Wells's remarks were brief, yet one could not but feel that they came from a master mind.

Mr. Lawson Tait struck a responsive chord in his audience by saying that an exact diagnosis in cases of acute intestinal obstruction is never made until the abdomen has been opened; and furthermore, that in a majority of cases the cause of the trouble is not apparent even then, nor is it advisable to search for it too curiously, as by establishing an artificial anus, at the most convenient point, you will always relieve, and generally cure, the patient! He has opened the abdominal cavity between seven and eight hundred times in all, and always on the median line in the cases under consideration. He also strongly advocated laparotomy as a remedial measure in peritonitis, having performed the operation twenty times with good results. He washes out the cavity of the peritoneum, inserts a drainage tube, and treats the case as one of ordinary suppuration. Mr. Tait evidently has great faith in abdominal section; more than most surgeons of even the most advanced school.

Mr. Oliver Pemberton, on the other hand, does not think it justifiable to open the peritoneal cavity in these obscure cases for the purpose of finding out what is the matter; and when an operation is necessary, he prefers the right groin to any other location in which to make an artificial anus.

Mr. J. H. Morgan referred to a few cases in which

¹ See this journal, August 2d, page 117.

considerable portions of the intestine had been removed with success. His own cases, few in number, requiring operation, were fatal. In one or two cases of obstruction from bands, he had noticed at the autopsy that the bands were ulcerating, which indicated that Nature was trying to correct the abnormal condition, and might have been successful had the vital powers not become exhausted.

Mr. Christopher Heath read a paper on the Primary Treatment of Fractures by the Plaster-of-Paris Bandage the use of which he strongly recommended in fractures of the lower extremity, but not in the upper. In Colles' fracture he considered Carr's splint the best in use. The sooner the plaster bandage is applied the better, as it serves to prevent swelling and pain. In cases of fractured patella with effusion he aspirates the joint and applies the plaster case over cotton. Fracture of olecranon is to be treated by flexing the arm to a right angle; a method which gave a good result in the only instance in which I have used it.

Mr. Stokes thinks that the less done in fractures of the patella the better, and that paraffine is as good as gypsum with which to stiffen bandages.

Mr. John Croft applies his favorite leg bandage, which is simply side splints made by wetting thick blanket cloth in plaster and binding it upon the leg.

The writer could not resist the temptation to describe the method of treating ordinary fractures of the leg, which is so popular at the Boston City Hospital, by means of the "Plaster Posterior," a method not alluded to by any of the other speakers.

An interesting article was read by Dr. John Fagan on Rapid Effusion of Blood into the Knee-joint Immediately after an Injury. He cited fourteen cases in which by aspiration, once or twice repeated, and followed by bandage pressure, he had obtained a cure in about three weeks in every case. Blood or serum was usually found in the joint. GEO. W. GAY, M. D.

"IMMEDIATE AND FORCIBLE REMOVAL OF THE PLACENTA AFTER ABORTIONS."

MR. EDITOR,—In your issue of August 2d I observe a note referring to my "advocacy of the immediate and forcible removal of the placenta after abortions," and to the exactly opposite recommendation of Dr. Hiram Von Liveringen, of Fort Wayne, Ind., who, in a recent article, "cautions us to let the placenta alone after abortion." I had read this article, but had not thought it worth my while to refute its author's criticism of my active treatment of retained placenta after abortion, because his criticism was based solely on an apparently willful misinterpretation of the word "forcible" used by me in my paper. But when a journal of the standing which yours occupies quotes my words with apparently the same meaning I deem it my duty to myself as well as to the method I advocate to say that the word "forcible" used by me in speaking of the removal of the secundines after abortion by the fingers or instruments does not mean *violent*. *Well directed and controlled, intelligent force* is quite a different thing from brutal, ill-applied force or violence. The force used in extracting a fetal head by obstetric forceps is certainly great, often apparently excessive, and still if well directed and carefully applied does no harm to mother or child. It is only the

excess of force badly managed which harms, and "it was in this sense that I used the word "forcible" in my article. I say expressly, in italics, "*. . . the secundines should be at once removed after expulsion of the fetus in every case of abortion in which such removal can be accomplished without force sufficient to injure the woman.*" And again, "force should be absolutely avoided" during the operation with the fingers and curette.

Surely, Mr. Editor, such language is sufficiently plain, and the advocacy of unlimited force in this operation cannot be charged against me. I cannot help thinking that much of the eloquence with which my critic depicts the evils of "force" [*sic*], and the benefit of "let alone" treatment in this class of cases, was wasted and uncalled for.

Yours truly, PAUL F. MUNDÉ.
20 WEST FORTY-FIFTH STREET, NEW YORK, }
August 8, 1883.

Miscellany.

THE RESPONSIBILITY OF ACCOUCHEURS AFTER INFECTIOUS EXPOSURE.

THE *Edinburgh Medical Journal* (July, 1883) groups together a series of communications recently made to the *Centralblatt für Gynäkologie* on the subject of the duty of a practitioner with regard to attending labor cases after exposure to septic materials. Dr. V. Swieicki introduces the discussion. He refers to the divergence of opinions on this point entertained by various authors, such as Winckel, who recommends exclusion for a fortnight, Zweifel, who recommends it for a week, Schröder, for two days, Martin for twenty-four hours, and Küstner, Ahlfeld, Macdonald, and others, who insist upon thorough disinfection of hands, finger-nails, clothing, and body of the physician or nurse to be all that is necessary, time being a matter of subordinate importance provided the disinfection is complete. Volkmann's opinion is also referred to as belonging to the latter class. The author, as a contribution to our knowledge of this subject, records the case of a medical student at Erlangen who examined a midwifery case six days after having opened a thorax, and who had, according to his own account, every day washed with carbolic water in the strictest manner. Before allowing him to examine, the author asked and obtained Professor Zweifel's permission for so doing. The patient, a iii.-para, had an easy labor, but was subsequently seized with diffuse peritonitis associated with right-sided parametritis, and passed through a well-pronounced attack of puerperal fever, being only able to leave her bed at the expiration of four weeks. The child also was infected, gradually lost weight, and died on the twelfth day. The sectio proved the septic nature of the affection. It has, however, to be noted that, besides the student, the author, a practitioner, and the chief midwife examined the patient. The author says that the practitioner had made no post-mortem examination recently, and that both he and the chief midwife on the same day examined another lying-in woman, as well as other puerperal patients, whose convalescence was normal. Relying on this case, the author thinks that abstinence from midwifery practice after making a post-mortem examination, or after a case of puerperal fever, is advisable.

Löhlein, contributing to the discussion in the same

periodical, believes that the physician, if he understands the principles of antiseptics, may so disinfect himself after contact with a dead body or a suspicious lying-in case that he may safely continue his midwifery practice. He cites his own experience during the last four years, during which he examined and treated in consultation numerous patients suffering from putrid abscesses, puerperal fever, etc., and attended meanwhile two hundred and ten midwifery cases in his own practice without any casualty from puerperal sepsis, and with only very occasional high temperatures. This immunity he traces to the thoroughness with which he disinfected the hands, using soap, nail-brushes, and five per cent. carbolic lotion. The chief point, he maintains, is not what is used, but how the application is made. He followed the principle of performing thrice the act of disinfection,—first, at the patient's house; second, at home, to which he hurried as soon as possible, in order that he might change his clothing and linen; and, third, before making another vaginal examination.

Dr. Fritsch gives his experience, stating that since 1872 he has never lost a puerperal patient, and has had only one serious lying-in case (parametritis), although he had conducted many severe deliveries, and had followed other practice almost uninterruptedly. In 1873 he treated a brother suffering from putrid pelvic abscess, and had to dress the wound daily. After every dressing he washed himself with a six per cent. carbolic solution. During this time he conducted two hundred and forty midwifery operations, and for the first time in the history of the Poliklinik of Hallé there was an entire year without a single death. The author argues that this was no mere chance, but the result of the adoption of thorough and intelligent antiseptic precautions.

Dr. Wiener, of Breslau, also contributes to the symposium. This author states that in the midwifery clinique from autumn, 1880, to Easter, 1882, during which time Spiegelberg, and, after his death, the author, had charge of it, emboldened by Volkmann's and Ahlfeld's example, students who had to do with infectious materials, such as cadaveric poison, etc., were permitted to undertake deliveries, Spiegelberg and himself proceeding on the principle that if antiseptics actually presented a reliable protection against infection it must do so in all cases and under all conditions. In the time mentioned there died twelve out of four hundred and seventy-one puerperal women; of these twelve, seven must at once be subtracted, in so far as one was brought into the clinique already intensely infected; another had uterine rupture, with the child escaped into the abdomen; two had stinking carcinoma of the vaginal portion; two had suffered severe injury during delivery, partially owing to instrumental assistance; and one had succumbed to hæmorrhage. There remained, accordingly, five fatal cases, equal to 1.06 per cent. of the deliveries, which, without the coöperation of other factors, were caused directly by infection. Of these five deliveries it is further to be observed that one woman had been examined outside the clinique by a female not a midwife; two were used for examination purposes. The writer points out especially that a large portion of the few fatal cases in these public clinics are the examination cases, where many students examine, and where by reason of some interesting peculiarity they are anxious to make out the condition accurately, really thereby using the finger more than is necessary. If

all who had touched a cadaver or cared for a case of puerperal fever were to exclude themselves from midwifery practice for a long time, they should, in consistency, do the same on every occasion of touching infectious materials, whether a putrid carcinoma or the pus from an opened abscess. That such exclusion would lead to intolerable difficulties is plain. But these difficulties must doubtless be reckoned with if the view is really correct that every one that has to do with decidedly infectious materials cannot disinfect himself completely in quite a short period. But this view is not supported by the experience of the clinique in Breslau or of many surgical institutions. The author believes that it is only necessary that the operator, be he surgeon or obstetrician, possess the necessary familiarity and acquaintance with antiseptic details and is convinced of their value. One must, as Volkmann points out, in any case in which he has to deal with infectious materials, *immediately* undertake a thorough washing with soap and nail-brushes, in a strong—that is, about five per cent.—carbolic lotion (any weaker one is inadequate), and especially must observe careful cleansing of the roots of and parts under the nails, so as to prevent in this way putrid materials from drying in or being imbibed into the deeper layers of the epithelium.

ON THE BEHAVIOR OF THE UTERUS IN PUERPERAL ECLAMPSIA AS OBSERVED IN TWO CASES.

DR. BRAXTON HICKS, in a paper read before the Obstetrical Society of London, reported in the *American Journal of Obstetrics* (July, 1883), remarked that the condition of the pregnant uterus during a series of epileptiform attacks had not been very closely observed, the general idea being that the uterus participated in the general excitement of the muscular system. Passages were quoted from different works on the subject in illustration of this. The author then described two cases in which he had carefully noticed the action of the uterus. In each of them, coincidently with a convulsion, a powerful and prolonged contraction of the uterus was observed. Between the convulsions the uterine action was natural. He could not state the exact relationship in point of time between the convulsions and uterine contraction. He did not think that uterine contraction alone caused the convulsion; for in the most severe cases of tonic or clonic contraction of the uterus convulsions did not occur. But there might in these cases be increased excitability. It had been suggested that increased force of pains might result from carbonic acid intoxication due to the convulsions. He thought the immediate supervention of uterine contraction on the convulsive paroxysms and the quietness of uterine action between them told against this view. The presence of these contractions, together with the disturbance of the heart and vascular system and the pupil, showed that the muscles of organic life were liberally affected during the paroxysms of eclampsia. These prolonged and powerful uterine contractions, as well as the carbonic acid poisoning of the mother's blood, were a source of danger to the fœtus, and, in its interest, speedy delivery was called for, if it could be effected without harm to the mother.

Deaths reported 2946 (no reports from Brooklyn and New Orleans): under five years of age, 1582: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 1151, diarrhoeal diseases 859, consumption 351, lung diseases 99, diphtheria and croup 84, typhoid fever 73, scarlet fever 31, malarial fevers 30, measles 24, whooping-cough 21, cerebro-spinal meningitis 18, puerperal fever five, erysipelas three, typhus fever two, small-pox one. From scarlet fever, Philadelphia seven, Chicago six, Baltimore five, Buffalo three, Boston and St. Louis two each, New York, District of Columbia, Pittsburg, Milwaukee, New Haven, and Holyoke one each. From malarial fevers, New York 13, St. Louis five, Philadelphia four, Chicago three, New Haven two, Charleston, Springfield, and Westborough one each. From measles, New York 12, Baltimore five, District of Columbia three, St. Louis two, Worcester and Cambridge one each. From whooping-cough, New York nine, Chicago and District of Columbia three each, Pittsburg two, Philadelphia, Boston, Baltimore, and Cincinnati one each. From cerebro-spinal meningitis, New York five, Buffalo three, Cincinnati two, Chicago, St. Louis, Worcester, Lynn, Springfield, Holyoke, Newburyport, and Northampton one each. From puerperal fever, Chicago, Boston, St. Louis, and Buffalo one each. From erysipelas, New York, Philadelphia, and Cambridge one each. From typhus fever, New York and Philadelphia one each. From small-pox, St. Louis one.

Nine cases of small-pox were reported in St. Louis, Buffalo three; typhoid fever 30, scarlet fever 21, diphtheria 20, and measles three in Boston; scarlet fever seven, diphtheria six in Milwaukee.

In 38 cities and towns of Massachusetts, with an estimated population of 1,152,391 (estimated population of the State

1,922,530), the total death-rate for the week was 26.53 against 28.43 and 22.22 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending July 21st, the death-rate was 21.3. Deaths reported 3523: acute diseases of the respiratory organs (London) 179, diarrhoea 491, measles 119, scarlet fever 84, whooping-cough 54, fever 32, diphtheria 29, small-pox (Birmingham three, Newcastle one) four. The death-rates ranged from 12.7 in Brighton to 29.7 in Newcastle-on-Tyne; Bradford 13.2; Bristol 16.9; Leeds 19.3; Birmingham 19.6; Leicester 19.7; Liverpool 22.6; Sheffield 23.1; London 23.5; Manchester 24.9. In Edinburgh 19; Glasgow 25.3; Dublin 22.7.

For the week ending July 14th, in 172 German cities and towns, with an estimated population of 8,658,348, the death-rate was 37. Deaths reported 6153; under five years of age, 4146; diarrhoeal diseases 740, consumption 490, lung diseases 400, diphtheria and croup 164, measles and rtheln 135, scarlet fever 69, typhoid fever 57, whooping-cough 41, puerperal fever 17, small-pox (Breslau two, Frankfurt a. M., Spandau, and Worms one each) five. The death-rates ranged from 14.9 in Elberfeld to 63.9 in Berlin; Königsberg 25.6; Breslau 43.5; Munich 46.6; Dresden 31.9; Leipzig 36.7; Hamburg 31.5; Cologne 46.5; Frankfurt a. M. 23.9; Strasburg 33.

For the week ending July 21st, in the Swiss towns, there were 31 deaths from consumption, diarrhoeal diseases 19, lung diseases 15, measles nine, diphtheria and croup three, whooping-cough three, typhoid fever two, scarlet fever one, erysipelas one. The death-rates were at Geneva 17.4, Zurich 16, Basle 15.9, Berne 20.3.

The meteorological record for the week ending August 4th in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM AUGUST 3, 1883, TO AUGUST 10, 1883.

MAGEUDER, DAVID L., lieutenant-colonel, and surgeon. The leave of absence extended one month. S. O. 89, Military Division of the Missouri, August 4, 1883.

FORWOOD, WILLIAM H., major and surgeon. To proceed to Fort Washakie, Wyoming, and Fort Ellis, Montana, on public business, and return. S. O. 87, Military Division of the Missouri, August 2, 1883.

WOODWARD, JOSEPH J., major and surgeon. Leave of absence granted on account of sickness, by S. O. 34, extended six months. S. O. 179, A. G. O., August 4, 1883.

BYRNE, CHARLES B., captain and assistant surgeon. Relieved from duty at Fort Craig, N. M., and assigned to duty at Fort Lewis, Colorado. Paragraph 3, S. O. 161, Department of the Missouri, August 6, 1883.

LAUDERDALE, JOHN V., captain and assistant surgeon. Granted leave of absence for two months, to take effect on or about the 15th inst. Paragraph 2, S. O. 90, Department of the Missouri, August 6, 1883.

OWEN, W. O., JR., first lieutenant and assistant surgeon. To proceed from Vancouver Barracks to Fort Walla Walla, W. T., and report to the commanding officer of the latter post for temporary duty. S. O. 101, Department of the Columbia, July 27, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING AUGUST 11, 1883.

GATEWOOD, J. D., passed assistant surgeon, orders to the Trenton revoked, and ordered to the Kearsarge.

SCOTT, HORACE B., assistant surgeon, detached from the Receiving Ship Franklin at Norfolk, on the 30th inst., and ordered to the Trenton on September 1st.

AUSTIN, A. A., passed assistant surgeon, detached from the Richmond, and waiting orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, APRIL 1, 1883, TO JUNE 30, 1883.

BAILHACHE, P. H., surgeon. To examine officers and cadets of the Revenue Marine Service. April 2, May 28, and June 4, 1883.

To proceed to New York, N. Y., to make arrangements for the care of seamen. April 30, 1883.

To proceed to Chattanooga, Memphis, St. Louis, Cairo, Evansville, Louisville, Cincinnati, Gallipolis, Wheeling, and Pittsburgh, as inspector. June 23, 1883.

MILLER, T. W., surgeon. Detailed as president of Board of Examiners. May 15, 1883.

Detailed as member of Board for the physical examination of cadets of the Revenue Marine Service. May 15, 1883.

WYMAN, WALTER, surgeon. Detailed as member of Boards for the physical examination of officers and cadets of the Revenue Marine Service. May 1, 15, and 28, 1883.

Detailed as member Board of Examiners. May 15, 1883.

MURRAY, R. D., surgeon. To proceed to Pensacola, Fla., and take charge of Quarantine Service. May 21, 1883.

GASSAWAY, J. M., surgeon. Granted leave of absence for ten days. April 21, 1883.

Detailed as recorder, Board of Examiners. May 15, 1883.

SMITH, HENRY, surgeon. Granted leave of absence for thirty days on account of sickness. June 14, 1883.

FISHER, J. C., passed assistant surgeon. Detailed as member of Boards for the physical examination of officers of the Revenue Marine Service. May 1 and June 4, 1883.

COOKE, H. P., passed assistant surgeon. Granted leave of absence for thirty days. May 15, 1883.

O'CONNOR, F. J., assistant surgeon. Relieved from duty at Detroit, Mich., and assigned to temporary duty at Boston, Mass. May 10, 1883.

GUIRERAS, JOHN, assistant surgeon. Granted leave of absence for thirty days, without pay. April 3, 1883.

ARMSTRONG, S. T., assistant surgeon. To proceed to Memphis, Tenn., for temporary duty. May 21, 1883.

BENNETT, P. H., assistant surgeon. Granted leave of absence for thirty days on account of sickness. June 26, 1883.

AMES, R. P. M., assistant surgeon. Granted leave of absence for fourteen days. April 3, 1883.

DEVAN, S. C., assistant surgeon. Detailed as medical officer, Revenue Steamer Corwin during cruise in Alaskan waters. April 16, 1883.

BEVAN, A. D., assistant surgeon. To proceed to Detroit, Mich., for temporary duty. June 11, 1883.

GLENNAN, A. H., assistant surgeon. To proceed to Norfolk, Va., for temporary duty. June 26, 1883.

APPOINTMENTS.

The following candidates, having passed the examination required by the Regulations, were appointed assistant surgeons by the Secretary of the Treasury, June 6, 1883:—

ARTHUR D. BEVAN, M. D., of Illinois, and
ARTHUR H. GLENNAN, M. D., of the District of Columbia.

BOOKS AND PAMPHLETS RECEIVED.—Transactions of the Mississippi State Medical Association at the Sixteenth Annual Session, held at Meridian, April 4-6, 1883, etc. Jackson, Miss. 1883.

A Rectal Obturator. By David Prince, M. D., Jacksonville, Ill. (Reprint.) 1883.

The Bead Suture. A modification of the Quilled Suture for Palatoplasty, etc. By David Prince, M. D., of Jacksonville, Ill. (Reprint.) Brooklyn, N. Y. 1883.

Two Cases of Hysteria: (1) Hysterical Hemi-Anæsthesia in a Man, following Injury; (2) Hysterical Anæsthesia of Special Sense accompanying Cutaneous Hyperæsthesia. By G. L. Walton, M. D. Boston.

Eleventh Annual Report of the Board of Health of the City of Boston for the Financial Year 1882-1883. Boston. 1883.

Lectures.

CLINICAL LECTURE ON ORGANIC DISEASE OF THE HEART.

DELIVERED AT BELLEVUE HOSPITAL, NEW YORK,
MAY 18, 1883.

BY PROF. AUSTIN FLINT, M. D.

GENTLEMEN, — To-day I propose to give you a kind of practical exercise in diseases of the heart, and, bringing before you a number of cases, none of which I have myself examined, endeavor to call to your attention such points in diagnosis and treatment as may arise in connection with them, and which may be of service to you in your study of this important subject. The first patient being now before us, I will proceed at once to make an examination in reference to his heart, without obtaining any history or asking any questions in reference to his present condition. On looking at the man we notice, in the first place, that he has no embarrassment in breathing, and that there is no cyanosis present. In regard to his heart we note that two movements are visible upon the chest-walls, one systolic and the other diastolic. Now let us see whether the heart is enlarged or not. The apex-beat is in the sixth intercostal space, on a vertical line with the nipple, which indicates that while the organ is enlarged, the degree of enlargement is not very great. On auscultation it is found that the first sound of the heart reaches its maximum intensity at this point. The next point is to find out how large a portion of the heart is uncovered with lung tissue. The normal area of cardiac dullness, as you are aware, is of the general shape of a right angled triangle, and here we find that this area of superficial dullness is at least double the normal size. We have thus made out the undoubted existence of a certain amount of enlargement of the heart. Whether this enlargement is due to hypertrophy or to dilatation is a very simple matter to determine. If there is hypertrophy there will be increased impulse, and if dilatation weakened impulse. It is well to remember, however, that the apex beat may be feeble while the impulse above that is quite strong. When this is the case it is due to a change in the shape of the heart, the organ having become more globular in outline. The next point in the differentiation between the two is to find out whether the impulse is of a heaving or sharp character. It is found to be of the latter, which results from dilatation; and we have in this case, therefore, enlargement of the heart with predominant dilatation.

In some cases enlargement of the heart is due to disease of the kidney, in which case the left side of the organ is principally affected, and in others to pulmonary emphysema, where the right side is enlarged. As a general rule, however, this pathological condition is dependent on valvular disease of the heart. There is certainly no emphysema present in this case, and presuming that there is no kidney trouble either, we will look for evidence of disease of the valves; and as the left side of the heart is far more commonly the seat of such affections than the right, we will make our examination of that first. We may have, as you know, either regurgitation or obstruction present, or both combined, and by means of auscultation we can usually

determine what the condition is without difficulty. On applying the stethoscope to the left side of the heart here I get a soft, bellows-like murmur, synchronous with the first sound of the heart, which reaches its maximum intensity at the apex, and which is also transmitted beyond the apex to the left. There is no presystolic murmur noticeable, and we decide, therefore, that there is present in this case a regurgitation from the left ventricle into the left auricle, or mitral regurgitation, as it is called. Auscultation of the aortic valves by placing the stethoscope in the second intercostal space, just to the right of the sternum, shows a negative result. The case, therefore, is a perfectly simple one; the enlargement of the heart depending on mitral insufficiency, which always leads to more or less increase in the size of the right ventricle, as is the case here.

One point of considerable practical interest in such a case as this is to compare the aortic second sound with the pulmonic second sound in order to form some idea of the degree of insufficiency existing. It is known that where there is hypertrophy of the right ventricle the pulmonic second sound is intensified, and in proportion, as a rule, as the second aortic sound is weakened, is the amount of mitral insufficiency present. In the present instance, I may say, there is a condition of affairs which can be tolerated almost indefinitely by the system, and I would warn you in cardiac affections generally not to form too hasty a prognosis of impending serious trouble.

Now, in order to make the case more complete, let us ask a few questions of the patient; but before doing so I will venture to predict with a very considerable degree of confidence that this man has had acute articular rheumatism at some period of his life. Yes, he says that he has had this disease, the first attack fifteen years ago, and the last three years ago. He does not give any history of endocarditis in connection with any of his attacks; but this is a complication which frequently escapes notice altogether. Yet its effects are apt to be of a permanent and serious character, and in this case it has undoubtedly led to the organic disease which is now present. In such a condition of the heart the patient after a time finds that he suffers more or less from shortness of breath in taking exercise which formerly produced no such effect, and that is the chief trouble here. The man says he "gets out of wind," and with this exception he is really quite well. This, then, is a perfectly typical case of simple mitral insufficiency, without mitral obstruction, and without any complicating disease of the aortic valves; typical as regards, first, the physical signs present; second, the connection of the trouble with acute articular rheumatism; and third, the general symptoms.

Finally, let us inquire what are the therapeutical indications in such a case as this? Too many practitioners under these circumstances resort at once to digitalis. Given a case of disease of the heart, and digitalis is prescribed as a matter of course. But in the present instance digitalis is not called for at all. All remedies which cause depression and disturbance of the system are contra-indicated, first, because they would accomplish no good, and, secondly, so far as they had any effect it would be an injurious one. What we have to do here is to see what the man needs to put him in the best general condition possible. It is of the most importance to him to have good, nourishing alimentation, and if his digestion is defective, he should have appropriate remedies to improve it. In

¹ Reported for the Boston Medical and Surgical Journal.

this case there is merely a question of toleration, and as long as the general system is in good condition, the heart is not likely to give rise to trouble. The patient has now been in the hospital a week, and, with the nourishing diet, rest, and freedom from anxiety which he has had here, he has in this short time already improved to a very appreciable extent, as I am given to understand.

As to the matter of dyspnoea it is too much the custom for physicians to tell their patients suffering from cardiac disease that they must be exceedingly careful about taking exercise for fear of evil results, but this kind of advice has a bad effect on such patients. In the first place it keeps their minds continually on the subject of their hearts, which of itself is very injurious, and, secondly, it deprives them of that amount of exercise which is essential to the maintenance of health, and which, indeed, as a rule, they could take perfectly well. The safest plan is to direct such patients to take just as much exercise as they can without inconvenience or discomfort.

In the case of our second patient, whom I now bring before you, we notice on inspection of the chest only one movement instead of two, as in the other, at the apex of the heart, while there is in addition a second movement at the base. The heart is undoubtedly enlarged because the apex beat, as you will observe, is considerably lower down than it ought to be. Unlike the former case it is also found much further to the left than its normal position, a point which leads us to infer the presence of mitral disease. In this respect the first case was an exception to the general rule, the apex beat being carried so little to the left that it would, perhaps, seem to indicate an aortic rather than a mitral affection. On account of the strength of the impulse in the present instance we infer that there is hypertrophy rather than dilatation of the heart.

On auscultation we get a systolic murmur at the apex which differs from that in the other case in being less loud, much lower in pitch, and not of such a marked bellows-like character. Again, however, there is no evidence of any mitral obstruction, but when we apply the stethoscope at the base we get with each systole a loud, rough murmur, which must therefore be a direct aortic murmur. But in addition, instead of the second sound of the heart there is found another rough murmur, so that we have here a systolic and diastolic aortic murmur besides the systolic mitral murmur. The latter is much weaker in tone than the aortic murmurs, but notwithstanding this it is quite possible that the mitral disease may be more serious than the aortic. The practical lesson to be learned from this is that it is never safe to judge of the gravity of disease of the heart from the intensity and quality of the murmurs heard. I find in this case distinct evidence of dilatation of the aorta (though not necessarily in the form of a sacculated aneurism) in addition to the cardiac disease. I would warn you, however, never to form a diagnosis of aortic aneurism from the roughness of murmurs heard at the base.

This patient is only twenty-eight, and therefore not of an age which entitles him to have aneurism, which, as a rule, occurs at a later period of life. I am quite sure, however, that there is dilatation of the aorta here, and when this occurs as early as the age of this man it is almost invariably due to one cause, namely, syphilis. This he denies having had, but as he also says that he has never had acute articular rheumatism I am afraid

we shall have to place the weight of pathological authority against the word of the patient.

On questioning him I find that notwithstanding the fact that he has an enlarged heart, with both mitral and aortic lesions, he is able to work hard, and that he manages to get along very well altogether with the exception of a pain in his side sometimes. His heart is really much larger than that of the other patient, but he suffers less inconvenience because the valvular disease is compensated for by predominant hypertrophy, while in the other case the heart has reached the limit of its growth. In the latter the cardiac walls have become more or less thinned, and the predominant dilatation gives rise to greater weakness and interference with respiration.

Our next patient is a Bohemian, who does not speak any English. On inspection and palpation we get two impulses, and find that the one at the apex is not so strong as a second one that is higher up. The apex being lowered and carried considerably to the left in this case also, we have a sufficient basis to warrant the guess that here again there is a mitral lesion. Auscultation reveals the presence of a loud, high-pitched, bellows-like systolic murmur, and there being no presystolic murmur we form the diagnosis of mitral regurgitation without obstruction, as in the other cases. At the base the only adventitious sound is an indistinct murmur, which is simply a transmission of that heard at its maximum intensity at the apex. We have again, therefore, a case of mitral insufficiency and enlargement of the heart, and as it is the right ventricle that is principally affected in the latter the pulmonic second sound ought to be intensified as compared with the aortic second sound. I find, in fact, that the difference between the two is so great that it convinces me that it depends on weakness of the aortic sound as well as the intensifying of the pulmonic, and therefore we are enabled to form some idea of the amount of regurgitation that is here present.

In the last patient whom we shall have time to examine to-day I find again the apex lowered and carried considerably to the left. There is, then, cardiac enlargement here also, and from the character of the impulse there can be little doubt that there is predominant hypertrophy rather than dilatation. The first sound of the heart also indicates this. In hypertrophy the first sound is loud, long, and booming, while in dilatation it is short, weak, and valvular in character. There is once more a mitral systolic or regurgitant murmur, and no direct mitral murmur indicating obstruction. In this case it is quite a feeble murmur, and, therefore, in marked contrast to that heard in some of the other patients. At the base there is found an aortic direct murmur, loud and rough, and an aortic regurgitant, feeble and soft. In connection with this case I would again impress upon you the caution of not judging of the gravity of cardiac disease from the intensity of the murmurs present. Twenty years ago there was connected with the house-staff of this hospital a young physician who had a well-marked aortic regurgitant murmur, yet ever since then he has continued in the active practice of his profession, and to-day the general state of his health is excellent. If I had time I could tell you of a large number of similar instances. Although this patient has enlargement of the heart, mitral insufficiency, and both aortic insufficiency and obstruction, I will venture to predict that he will do well because his system has already tolerated

this cardiac condition for a considerable time, and the symptoms of the case do not now indicate any immediate serious trouble such as we would apprehend if there were present dyspnoea without taking exercise, cyanosis, and general dropsy.

GLYKOGEN.¹

BY JOSEPH W. WARREN, M. D.

Of all the bodily organs common to both sexes no one, perhaps, has attracted the attention of the medical profession so constantly and so universally as the liver. Its size and vascularity, no less than its intimate topographical associations with the heart and the digestive tract, were enough to justify the importance attributed to it, and to render reasonable the part it has played in the theory of disease as well as among the mysteries of physiology. One other organ — the uterus — has been a worthy rival in offering an easy explanation of bodily trouble and a much more convenient point of attack, but fortunately somewhat less than half the children born present this ætiological combination. Modern medical work, pushing back gradually but surely the limits of exact knowledge, has robbed the liver of much of its mystery, and brought down such terms as melancholy and biliousness from the curious position they once occupied. We are still far enough from knowing with any exactitude what the liver, or, indeed, almost any organ of the body, really does, but we have taken the first great step, at least, on the road to knowledge; we have found the way to an understanding; we have accepted the experimental method in physiology and pathology, and, thorny as the path is along which this leads us, every sign-post we meet assures us that we are slowly perhaps, but none the less surely, reaching the goal of our desires.

The experimental method calls for the patient, laborious work of many investigators, and their results are not always easily grasped and understood by those who cannot regularly follow them in detail, and much that is done is published in journals or pamphlets not very accessible to the general practitioner. I have ventured, then, to ask your permission to-day to act as a modest filter in presenting, somewhat popularly and as concisely as may be, some of the results of work done by many authors in the past few years, and bearing upon one function of the liver.

I mean its glykogenic function, or, more generally, the present state of our knowledge of glykogen. I fear that what I shall have to say will seem to many of you exceedingly negative, for it tears down some older views and builds up but little. In science we have no dogmas to maintain, and we are true to a theory or a hypothesis only so long as the facts bear it up. Like the mountain climber, we must often descend to get a new line of advance when the old one has led us on as far as it may. It is the tyro who sticks to the bee-line and sneers at chasm and crevasse.

We are so accustomed nowadays to think of glykogen that it is well, perhaps, to be reminded that the recognition of it is really of very recent date. There are members enough of this Society, still hale and

hearty and in busy practice, who never heard or dreamt of any such substance until they had been in active work for years. It is, indeed, not quite thirty years since the discovery was made that the liver contained a starch-like body which, under certain conditions, could be changed into sugar. This discovery is associated with the name of the great Frenchman, Claude Bernard, although Hensen, a German, seems to have made the discovery independently at about the same time. Not long before Bernard had found sugar in the liver, and had described its production as a new hepatic activity, so that when yet another new liver substance was found capable of easy transformation into sugar the name of sugar-former, or glykogen, was naturally suggested.

Circumstances have combined to attract much attention to its study, the hope of finding the solution of the pathological problem associated with diabetes being, perhaps, the most prominent in the mind of the practitioner.

Physiologists have long recognized that the glykogen problem has far more importance than an explanation of such a disease as diabetes mellitus can be, that it promises to open the way to a clearer insight into the grand secret of nutrition itself. In the light of some of the newer work in this direction the way promises to become clearer, but our light is yet but as the poor tallow dip of our ancestors in comparison with the electric light we hope to have. The whole problem of nutrition is very far from a solution, the number of equations being altogether too small for the unknown quantities. Our position resembles that of the impecunious man ignorant of culinary mysteries who watches the entrances of a great hotel. He sees the ruddy beef and much dimpled bottle which go in, but fails to understand their exact relations to the ruddy cheeks and ruddier noses which go out at the front and the garbage carried off at the back.

The chemical story of glykogen can be very briefly told. It is, when dry and pure, a white powder, perfectly amorphous, showing nowhere the least tendency to crystallize. It is soluble in water, at least it seems to go into a solution of a peculiar opalescent character. It rotates the plane of polarized light to the right three, or even four, times as much as glucose. The opalescent solution can be cleared by the addition of an alkali or an organic acid, but it is probable that a modification of the glykogen is brought about by this treatment. It is precipitated by alcohol and by ether, in other words, is insoluble in them. The solution, which by the way is tasteless, filters readily but diffuses very slowly.

The ordinary method for obtaining glykogen is simple in principle, and for its best form we are indebted to Brücke. The tissues to be examined are minced as finely as possible, and extracted in hot water as long and as often as anything is taken up. The filtrate is then freed from such albuminoid bodies as may have passed into the hot solution, and the glykogen is precipitated by alcohol, washed, redissolved, and again precipitated until the desired degree of purity is attained. It is usually considered easy to obtain perfectly pure glykogen, free from salts and leaving no ash upon combustion, but there is apparently a discrepancy in the statements, for only a few weeks ago a cautious worker in this department reported that he found perfectly pure glykogen which he had very carefully prepared to remain in solution despite the addition of a

¹ Read before the Massachusetts Medical Society, June 12, 1883.

this case there is merely a question of toleration, and as long as the general system is in good condition, the heart is not likely to give rise to trouble. The patient has now been in the hospital a week, and, with the nourishing diet, rest, and freedom from anxiety which he has had here, he has in this short time already improved to a very appreciable extent, as I am given to understand.

As to the matter of dyspnoea it is too much the custom for physicians to tell their patients suffering from cardiac disease that they must be exceedingly careful about taking exercise for fear of evil results, but this kind of advice has a bad effect on such patients. In the first place it keeps their minds continually on the subject of their hearts, which of itself is very injurious, and, secondly, it deprives them of that amount of exercise which is essential to the maintenance of health, and which, indeed, as a rule, they could take perfectly well. The safest plan is to direct such patients to take just as much exercise as they can without inconvenience or discomfort.

In the case of our second patient, whom I now bring before you, we notice on inspection of the chest only one movement instead of two, as in the other, at the apex of the heart, while there is in addition a second movement at the base. The heart is undoubtedly enlarged because the apex beat, as you will observe, is considerably lower down than it ought to be. Unlike the former case it is also found much further to the left than its normal position, a point which leads us to infer the presence of mitral disease. In this respect the first case was an exception to the general rule, the apex beat being carried so little to the left that it would, perhaps, seem to indicate an aortic rather than a mitral affection. On account of the strength of the impulse in the present instance we infer that there is hypertrophy rather than dilatation of the heart.

On auscultation we get a systolic murmur at the apex which differs from that in the other case in being less loud, much lower in pitch, and not of such a marked bellows-like character. Again, however, there is no evidence of any mitral obstruction, but when we apply the stethoscope at the base we get with each systole a loud, rough murmur, which must therefore be a direct aortic murmur. But in addition, instead of the second sound of the heart there is found another rough murmur, so that we have here a systolic and diastolic aortic murmur besides the systolic mitral murmur. The latter is much weaker in tone than the aortic murmurs, but notwithstanding this it is quite possible that the mitral disease may be more extensive than the aortic. The practical lesson to be learned from this is that it is never safe to judge of the extent of disease of the heart from the intensity and character of the murmurs heard. I find in this case no evidence of dilatation of the aorta, though the disease is in the form of a sacculated aneurysm, and it is not the cardiac disease. I would therefore advise you to form a diagnosis of the nature and extent of the disease from the nature and position of the murmurs heard.

This patient is a man of an age which, as a rule, occurs with a certain degree of frequency, however, and when this disease is almost invariably fatal. This he denies, but has never had

we shall have to place the weight of pathological authority against the word of the patient.

On questioning him I find that notwithstanding the fact that he has an enlarged heart, with both mitral and aortic lesions, he is able to work hard, and that he manages to get along very well altogether with the exception of a pain in his side sometimes. His heart is really much larger than that of the other patient, but he suffers less inconvenience because the disease is compensated for by predominant hypertrophy while in the other case the heart has reached the limit of its growth. In the latter the cardiac muscle becomes more or less thinned, and the predilatation gives rise to greater weakness and distress with respiration.

Our next patient is a Bohemian, who speaks no English. On inspection and palpation I find strong impulses, and find that the one at the apex is as strong as a second one that is higher up. The apex being lowered and carried considerably to the left in this case also, we have a sufficient ground to guess that here again there is a dilatation. Inspection reveals the presence of a bellows-like systolic murmur. At the apex a systolic murmur we form the impression of gurgitation without obstruction. At the base the only audible murmur, which is simple, is at its maximum intensity. Therefore, a case of dilatation of the heart, which is principally affected by the aortic second sound, and the murmur between the two depends on the intensification of the sound enabled to be heard at the base.

In the present case we amine to consider the larger impulses in the infant sound the dilated heart.

The

ent for the liver must be of great importance in bringing about further changes. The glycogen in the muscle but little is of value can hardly be questioned. It is already mentioned, that large quantities of glycogen are present in the muscular tissue after feeding, and during fasting there is a marked diminution of the quantity. A similar diminution seems to occur in the liver. The exact extent to which muscular glycogen is used for the total amount of glycogen in the body is not yet made out, for in some of the cases of inanition the conditions of hunger were much complicated by bodily activity. Until very recently the inanition was supposed to be associated with a rapid glycogen consumption, the acid reaction of such a condition being associated with the changes of the sugar which the glycogen had been transformed. It is now found, however, that the rigor mortis itself is not necessarily associated with a lessening of the glycogen, if putrefactive changes be avoided; if these be prevented then the glycogen is rapidly used up. The true solution of the acidification of the rigid muscle has not yet been reached, for it does not follow that more acid is really present because the acid reaction has increased, as two observers have shown for the acidification of tetanus.

It seems that there is a direct relation between glycogen and muscle work, for there are experiments showing that the working muscle can saccharify the glycogen on the one hand, while, as Kobert has very recently shown, the introduction of glycogen increases the amount of work a muscle can perform.

If we wish, then, to summarize briefly, we may say: The presence of glycogen is closely associated with the first steps of nutrition. This is not only clearly shown by its increase in various tissues after taking food, but its presence in large quantities in the embryo—in rapidly growing cells—would seem to indicate its prime importance. Activity and hunger lessen its amount, but this may be interpreted in two ways, since the disappearance may be only the normal transformation for which no compensation is furnished, or its transformation may be the actual source or one source of the muscle power. But one point should not be left out of sight, that wherever the appearance of any putrefactive change can be assumed we shall find a marked diminution of glycogen, and it becomes a serious question how far the disappearance of glycogen as reported in all less recent investigations has been due to some putrefaction, in other words, has not been merely functional. In these times when the body no less than the air is full of bacteria and germs, we may fairly have our suspicions of earlier work, for the golden age of science lies in the future, and not in the past.

It is thought by some that the most important part of a scientific paper, as of a sermon, lies in the personal application. The most natural one here would be with reference to diabetes, and that can, frankly, be but negative.

Concerning diabetes, however, there are a few things to be borne in mind. In the first place, as Von Wittich has happily remarked, it is by no means certain that what goes by this name is really only one disease; it may be that a number of different complaints have been classed together simply because our attention has been directed mainly to one noteworthy feature common to them all, the excretion of sugar. But this is not the only important feature, and the excretion of

considerable amount of alcohol, while the addition of a minute amount of chloride of sodium caused a complete precipitation. It is worthy of remark that an analogous behavior of albumen was reported some years ago; that is, that albumen, when perfectly freed from any admixture of salts, lost many of its peculiarities of coagulation.

Glykogen treated with iodine assumes a red color, like that of good port wine. Some varieties of coloring have been reported for the glykogen obtained from various sources, but there is no great regularity in them, and no sufficient explanation has been found for such irregularities.

Under the influence of various acids, and particularly of numerous ferments, glykogen becomes more or less changed, and these changes can be to some extent traced by the behavior of the body to iodine, so that a long series of intermediate substances may perhaps be postulated, bearing a relation to glykogen and sugar like that borne by the various dextrines to the starches and their sugar products.

In so far, however, as the postulation of such substances depends upon the iodine reaction we ought to bear carefully in mind that this is frequently very misleading. The end product of these changes interests us most. It is a sugar, and was for a long time supposed to be grape sugar, — glucose. Within a few years it has been shown that the action of the ferments (diastase as well as the salivary and the pancreatic ferment) on glykogen produces a sugar not unlike glucose, and yet different enough to be of importance. This sugar, known as maltose, has the noteworthy peculiarity of reducing cupric oxide much less than glucose does. According to some older investigations of Nasse there is perhaps yet another sugar to be distinguished from dextrose and maltose, which he proposed to name *ptyalose*. The important point, however, is this, that for years many have assumed dextrose to be the sugar obtained from glykogen by the action of the ferments or the acids, and have calculated the amount of glykogen from the reduction of cupric oxide by this sugar. If, now, we have a mixture of dextrose and one or more other sugars of much less power in reducing cupric oxide, evidently many of the deductions hitherto made may call for much modification.

The exact chemical composition of glykogen is not certainly known. It belongs to the carbohydrates, that is, it contains only carbon, oxygen, and hydrogen, these latter in the same proportions as water. Hoppe-Seyler gives it the formula: $C_6H_{10}O_5$.

Despite the variety of sources from which it has been obtained no marked difference has been found, except the slight irregularities in the behavior to iodine. We are not, then, as yet justified in speaking of different glykogens. Had we to do with a crystallizable substance we might, perhaps, recognize differences which are not now apparent.

If we were to name the sources from which we can obtain glykogen, it would be necessary to mention not only almost all the tissues of the vertebrate body, but we should have to include many other forms of animal life, for it has been found notably in mollusks and in some of the crustacea, and in large quantities in insects and many worms. It is, perhaps, a significant fact that no such thing as a vegetable glykogen has been found, — a fact, too, that has never received the attention it probably deserves.

It interests us especially to remember that the mam-

malian liver and muscular tissues contain very considerable amounts of glykogen, and this is true not only of the developed animal but also of the new-born, which have not yet received any nourishment save through the uterus or in the egg.

The presence of glykogen in the muscles is no new discovery, but it is surprising to see how very little attention is paid to it in the text-books. The amount of muscle glykogen is evidently not appreciated by most writers. The percentage of glykogen found in muscular tissue is small as compared with that of the liver, but if you will take the trouble to figure it out you will find that the total amount in all the muscles is oftentimes not very much less than that found in the liver. That this is actually the case was demonstrated some three years ago by Boehm, who worked up the liver and most of the muscles of a cat, and obtained nearly the same amount of glykogen from each tissue. At the same time he demonstrated the exceeding difficulty of fully extracting the muscles, and showed that his own previous results in this direction had involved a possible error of twenty-five per cent. The reason of this is to be found in the tenacity with which the coagulated muscle tissue retains the glykogen, it being much more difficult to prepare it for extraction than the softer tissue of the liver. In view of this fact — and I see no reason to question the trustworthiness of Boehm's statement — it is clear that all previous observations on the quantity of muscle glykogen and its behavior under various influences are subject to a very considerable correction.

The form in which glykogen is stored up in the muscles is unknown. There are, I think, no investigations reported in which it has been seen in any such tissue. For the liver we have somewhat more definite observations. In the cells of this organ conglomerations have been seen whose behavior to iodine is such that we are warranted in supposing that we have actually the glykogen stored up in the cell itself, just as reserve starch grains may be seen in plants. Besides these shiny clumps of glykogen in the cells there may, of course, be more or less in the surrounding liquids. Whether a similar storage takes place in the muscle we do not know; the liver may be a magazine from which the muscles are supplied.

Concerning the conditions which favor the increase of the glykogen in the liver or the muscles, as well as the conditions favoring its disappearance, there is unfortunately much disagreement, despite the very large number of experiments reported.

On one point, however, there is general unanimity, that feeding increases while hunger distinctly decreases the amount of glykogen. Among the foods, those containing sugar, or whose digestion produced much sugar, have seemed especially efficacious; but it had been found that many other materials, as flesh, for example, or fibrine (to which no suspicion of an admixture of a carbohydrate could attach itself), were also capable of causing a distinct increase of our substance in the liver.

The influence of the carbohydrates admits of various explanations. The glykogen might be formed directly from them by some synthetic process, which prepared it to be stored up until wanted. Or the carbohydrates might take the place of the glykogen already in the liver, and being constantly stored up there, but only to be normally carried off again nearly as rapidly. In this case it will be seen that an increase of the glykogen

could take place running parallel with the inflow of the carbohydrates, just as a mill-pond may fill up or remain full if the busy mill can only get its power from some other source. Yet another simple explanation offers itself: A portion of the carbohydrates may be changed directly into glycogen, the remainder being worked up otherwise and acting in some way as a stimulus to the formation of glycogen out of other substances.

Not a little of this difficulty has been occasioned by the very natural view that the liver sugar came directly from the glycogen, — a view that now bids fair to undergo very marked modification. This association of ideas dates back to the very discovery of glycogen, and saccharification has been, tacitly at least, assumed as the change which it must undergo, and what is more, the sugar found anywhere in the body has often been referred to glycogen as its forerunner.

Sugar is found in the liver, and its increase after death has long been known, and a decrease of glycogen has been postulated, or even seemed to be shown, to be associated with this change. It does, indeed, look as though some such relationship really did exist in the rabbit, which, with the frog, has always held a high place in the practical friendships of the physiologist. Be that as it may, this view of the relations of the liver sugar has recently — in the past few years, I mean — received a severe blow. The assumption that some ferment in the liver changes glycogen into grape sugar has lost much of its validity; for it has been shown that while glycogen can be changed by acids into glucose, the usual change by ferments is into one or more other sugars of a different character, for which the general name ferment sugar has been proposed, and up to the present time the demonstration of such a ferment — a specific saccharine ferment in the liver — has not been made. Not only this — it has also been clearly shown that the development of sugar in the liver as a post-mortem change is the development of grape sugar, and is not associated with a diminution of the glycogen, or, at least, that the disappearance of the glycogen bears no relation to the development of sugar. Of greater importance still is the demonstration that the liver is capable of forming sugar out of albuminoid material, or, more exactly, out of peptone. It has been found that the introduction of peptone through the intestinal tract, or through blood-vessels, causes an increase of the liver sugar. It has further been shown that this transformation of peptone is actually performed by the liver cells themselves. It is perhaps known to many members of the Society that in finely-minced fresh tissue a sufficiency of cells may be kept alive at a low temperature, and by the aid of properly aerated blood, for a sufficient length of time to enable us to demonstrate the actual power of such cells in producing chemical changes which are more or less characteristic of the organ. In this way the synthetic power of various groups of cells has been shown, and the method promises to be of great value in other directions. Seegen has found (about two years ago) that such liver cells transform peptone into sugar, while no development of sugar takes place in the cells which are simply exposed to the aerated blood. Thus the alteration of albuminoid material would seem to be a distinct function of the liver, — a function, then, which is carried on independently, it may be, of the glycogen present. This may prove to be a function of other organs, — the point is not yet investigated, —

but its establishment for the liver must be of great value in understanding further changes.

Of the value of glycogen to the muscle but little is known. That it is of value can hardly be questioned. We know, as already mentioned, that large quantities of it are found in muscular tissue after feeding, and that hunger causes a marked diminution of the quantity, and a similar diminution seems to occur in the working muscle. The exact extent to which muscular work lessens the total amount of glycogen in the body is not clearly made out, for in some of the cases of diminution the conditions of hunger were much complicated by bodily activity. Until very recently the rigor mortis was supposed to be associated with a great glycogen consumption, the acid reaction of such tissues being associated with the changes of the sugar into which the glycogen had been transformed. Boehm found, however, that the rigor mortis itself is not necessarily associated with a lessening of the glycogen if putrefactive changes be avoided; if these be present then the glycogen is rapidly used up. The true solution of the acidification of the rigid muscle has not yet been reached, for it does not follow that more acid is really present because the acid reaction has increased, as two observers have shown for the acidification of tetanus.

It seems that there is a direct relation between glycogen and muscle work, for there are experiments showing that the working muscle can saccharify the glycogen on the one hand, while, as Kobert has very recently shown, the introduction of glycogen increases the amount of work a muscle can perform.

If we wish, then, to summarize briefly, we may say: The presence of glycogen is closely associated with the first steps of nutrition. This is not only clearly shown by its increase in various tissues after taking food, but its presence in large quantities in the embryo — in rapidly growing cells — would seem to indicate its prime importance. Activity and hunger lessen its amount, but this may be interpreted in two ways, since the disappearance may be only the normal transformation for which no compensation is furnished, or its transformation may be the actual source or one source of the muscle power. But one point should not be left out of sight, that wherever the appearance of any putrefactive change can be assumed we shall find a marked diminution of glycogen, and it becomes a serious question how far the disappearance of glycogen as reported in all less recent investigations has been due to some putrefaction, in other words, has not been merely functional. In these times when the body no less than the air is full of bacteria and germs, we may fairly have our suspicions of earlier work, for the golden age of science lies in the future, and not in the past.

It is thought by some that the most important part of a scientific paper, as of a sermon, lies in the personal application. The most natural one here would be with reference to diabetes, and that can, frankly, be but negative.

Concerning diabetes, however, there are a few things to be borne in mind. In the first place, as Von Wittich has happily remarked, it is by no means certain that what goes by this name is really only one disease; it may be that a number of different complaints have been classed together simply because our attention has been directed mainly to one noteworthy feature common to them all, the excretion of sugar. But this is not the only important feature, and the excretion of

sugar, in smaller quantities to be sure, is met with under conditions which seem to be physiological. The experiments of Eichhorst which bear upon this point have not, I believe, been repeated. The excessive amount of water excreted is, perhaps, one indication of changes which are not all explicable by the hypothetical liver ferment. If we may trust the reports on this point the excretion of water is often greater than the amount taken into the body would cover, yet there is here room enough for suspicion that water may have been surreptitiously introduced. We ought not to forget, too, that the water very frequently bears no relation to the amount of sugar excreted, and that an enormous increase of the urine is met with under totally different conditions, as in the insipid form of diabetes and in hysteria.

In the sugar form of the disease in question there is a marked increase in the outflow of nitrogenous compounds, principally urea. This is often explained as a more thorough washing out than normally, an ingenious explanation to be sure, but not in full accord with what we think we know about the physiological excretion of urea. As Oppenheim has shown, the increase in the water output under physiological conditions is associated with an increase of urea, but only at first, and to be followed by a diminution which speedily reduces the excretion to its average. Not so in diabetes mellitus; here the increase in urea is marked and continues, and it remains high, too, when the food supply is so regulated that no increase in the nitrogenous inflow can be used to explain the increased outflow. One other circumstance, for which, however, the careful verification by further observations is desirable, shows that the tissue change in the diabetic differs materially from that of the natural man. It has been demonstrated clearly enough for our acceptance that muscle work where the individual is in a state of nitrogen equilibrium, as it is called, is not associated with an increase in the nitrogenous excretion, but in diabetes it has been found that very moderate muscular effort may produce a marked increase of these products, an observation which would seem to contrast curiously with the reported improvement in some diabetics when induced to work their muscles.

The other results of the treatment of diabetes mellitus are not in full accord in furnishing an explanation of the disease. If we read over the numerous dietaries proposed for the diabetic patient as we find them collated, for example, in Bauer's recent monograph, we must be struck by the immense variety in the limitations to which doctors have subjected their patients. There is a practical agreement but in one point, the general avoidance of carbohydrates, and even here the milk treatment and, possibly that with koumiss, forms a notable exception.

This I suppose we must accept as a fact of experience, that the condition of the diabetic generally improves under a regimen where the carbohydrates are avoided. The difficulty lies in the theoretical deduction which this observation permits us to make. In other words the connection between the sugar which is formed by digestion and that found in the urine is not clear. We have good reason to believe that the carbohydrates when digested form not altogether grape sugar, but other and different sugars, and it does not follow that these are so easily transformed into grape sugar, although they may be so changed.

The use of a careful meat diet has been a main stay

in practice. When we come to analyze it, however, as a support for any theory, we are met by a serious difficulty. Digested meat furnishes peptone, which when taken up can be transformed by the liver into grape sugar, which is the very sugar of diabetic urine.

Then, too, the transformation of glycogen by any known normal ferment no less than that of the carbohydrates so rigidly avoided by diabetics does not give us grape sugar, but another or, perhaps, various other sugars. If this be so, the theory that finds in diabetes only a rapid transformation of glycogen into sugar must look about for some new props.

A CASE OF THROMBOSIS OF THE STRAIGHT CEREBRAL SINUS.

BY T. M. ROTCH, M. D.

THE following case occurred at the West End Nursery, where it was under the care of Dr. H. C. Haven. A boy, six weeks old, was admitted to a bed in the house January 6, 1882. The parents were Americans, and so far as could be ascertained were healthy; the mother died of septicæmia following the birth of this infant, and the infant had never been put to the breast, but had had good care, and had been fed on cow's milk and water, on which it thrived, and it was apparently, on entering the nursery, a strong, healthy infant, weighing 4805 grammes, which at six weeks is decidedly greater than the average, for allowing the average weight of the male infant at birth to be 3250 grammes, and the gain per day, giving a liberal allowance, thirty grammes, the weight of an infant six weeks old should be 4510 grammes, making this especial infant weigh 295 grammes more than the average infant of the same age.

The infant was put on the usual diet given at the nursery to infants six weeks old, namely, one half milk and one half water, and he seemed to thrive during the first week, the appetite being good, and there being two or three apparently well digested dejections daily. He slept well, and no one would have known that anything was the matter with him if he had not been carefully weighed and found to be steadily losing.

The following is the record of his weight from the time of entrance, January 16th, until his death, January 30th:—

Date.	Grammes.	Gain or Loss.
January 16th.	4805	—
January 18th.	4655	Loss 150
January 20th.	4630	Loss 25.
January 21st.	4595	Loss 35.
January 22d.	4610	Gain 15.
January 23d.	4590	Loss 20.
January 24th.	4425	Loss 65.
January 25th.	4420	Loss 5.
January 26th.	4420	Loss 0.
January 27th, 8.30 A. M.	4110	Loss 310
January 27th, 8 P. M.	3995	Loss 115
January 27th, 7 P. M.	3925	Loss 70
January 28th.	3845	Gain 20.
January 29th.	3905	Gain 20.
January 30th.	3735	Loss 280.

January 23d, the loss in weight being very evident, the amount of milk was increased, but as the loss continued, barley water was substituted for the water. The barley water, however, was not relished, and was vomited; he was therefore on the 26th again put on

milk and water, but vomited twice, and on the 27th had one thin, watery discharge from the bowels. Mellin's food was then given.

January 28th he did not look well and seemed weak; brandy was given, and a wet nurse, whose milk was eleven days old, was procured; he nursed pretty well at first, but afterwards would only nurse for a few minutes. At seven P. M. he was carefully examined by Dr. Haven and myself with the following result: Temperature 38° F.; respiration natural, 35. No cough; pupils natural and contract well; fontanelle very slightly depressed; does not seem to be in pain, but is rather feeble. Auscultation and percussion of lungs and heart normal. No enlargement of spleen or liver detected. Nothing abnormal in mouth or throat.

January 29th had a natural yellow dejection. Vomited considerably during the day whenever food was given.

Six P. M. Rejected breast; pupils contracted; rhythmical contractions of arms and legs first on one side and then on the other; opisthotonos of upper part of spine; head and eyes drawn to the right; no rigidity or paralysis of legs or arms. Fontanelle not depressed. Rapid contractions of eyelids first on one side and then on the other.

January 30th. Six rather watery dejections. The muscular contractions ceased, but the opisthotonos continued until death at 6.30 P. M., when it disappeared.

Autopsy fifteen hours after death. Slight rigor mortis present. Body small, somewhat emaciated. Face thin and pinched.

Calvaria removed without difficulty. Nothing noticed on internal surface of dura mater. In the straight sinus, and in the portion of the superior longitudinal immediately adjoining this, was a firm red clot slightly decolorized in parts, but easily removed from the vessels. The other sinuses contained a little loosely clotted blood.

The surface of the brain was moist, and the spaces between the convolutions were slightly opaque and cloudy from the presence of a serous fluid. The blood vessels of the pia mater were injected.

Upon opening the lateral ventricles and turning back the fornix, the floor of the ventricles was seen covered with numerous thromboses of the blood-vessels, the surface universally reddened, the ependyma ragged and infiltrated, and a bloody serous fluid was found free in the cavity of the ventricles. The veins of the choroid plexus were filled with dark clotted blood which was directly continuous with that found in the straight sinus. The substance of the brain was moist.

The spinal cord presented a moderate injection of the vessels of the pia mater.

Both sides of the heart contained dark loose clots. The lungs were slightly oedematous.

The other organs presented nothing abnormal.

Diagnosis. Sinus thrombosis. Intra-ventricular hæmorrhage and softening of the floor of the ventricles. Oedema of the lungs.

As a summary of the case we have an infant, six weeks old, apparently strong and well on January 16th, losing over 200 grammes in a week up to January 23d without showing any other symptom of disease. Then on the 27th losing 495 grammes, and attacked two days later with convulsions, followed by death, and presenting at the autopsy nothing abnormal excepting a capillary hæmorrhage into the ventricles caused by a thrombosis of the straight cerebral sinus.

THE EARLY SYMPTOMS OF GENERAL PARALYSIS OF THE INSANE.¹

BY WILLIAM B. GOLDSMITH, M. D., OF DANVERS.

As physician in hospitals for the insane I have received many cases of general paralysis in which there had been an entire failure to appreciate correctly the at least possible import of various symptoms appearing before the unmistakable ones, which failure was sometimes attended with serious injury to the patients or others; for in disorders affecting the organ which controls the individual in his moral obligations, professional duties, social relations, and business transactions, the early recognition even of disease which we are forced to regard as incurable has more practical importance than exists in disease of other organs where an early accuracy of diagnosis often simply hastens the "verdict of despair" to the patient without benefiting his fellows, and among the various forms of mental disorder there is probably none which, in proportion to its frequency, so often, before its recognition, ruins the laboriously acquired and carefully guarded reputation of a lifetime, or involves relatives in scandal and financial reverses.

This failure of appreciation of early symptoms is, probably, partly because general paralysis, unlike most other forms of disease attended with mental decay, does not usually select its victims from those who have inherited weak and unstable nervous organization, but from the capable and vigorous in whom no one expects weakness to show itself, and partly because certain mental symptoms are so striking that we are liable to identify them with the disease, and not recognize it without them.

My remarks are based on an analysis of the histories of one hundred cases, and I think that they possess more accuracy as to fact than the average of such histories, because I have taken the cases of such patients only as had been under the careful observation of friends whom I believe to be intelligent and reliable.

This plan is open to the objection that the facts are largely obtained from non-medical and non-expert observers, but this is a source of error that cannot be avoided in studying mental disease, because the earlier symptoms have usually persisted some time before the case comes to the general practitioner, and still longer before it reaches the specialist, and as subjective examinations as to previous history cannot be considered reliable the observation of friends is our only resource; and it may be said in favor of the accuracy of my facts, that friends are much more likely to recall slight changes in a retrospect, and to frankly tell the whole truth concerning mental symptoms when they have become sufficiently marked to render it desirable to send the patient to a hospital, than earlier when they feel anxious to cover up improprieties and weaknesses. It is also true of these cases that they were selected at a time when the diagnosis was unmistakable, so that whatever may be said as to the occurrence of similar nervous symptoms in patients who do not become general paralytics, it is undoubtedly true that they were in these patients the warnings of that disease; and my aim is not so much to record the symptoms after they have become sufficiently characteristic for a certain diagnosis, as to show what are actual danger signals

¹ Read at the annual meeting of the Massachusetts Medical Society, June 13, 1883, and recommended for publication by the Society.

that should render the physician alert and observing, the recognition and observance of which would, I am sure, prevent much financial loss as well as danger to individuals, and unjust condemnation by legal tribunals and society; and it is reasonable to suppose that the nearer the beginning we start the more likely we are to prevent the dire ending which we now regard as inevitable. That these signals will be most varied and inconstant follows from the nature of the disease they indicate, as we must remember that there is no variety of nerve tissue in the cerebro-spinal or sympathetic system which has not been proved to suffer degenerative lesion consequent on this disease, or which has not been claimed, with fair assurance of accuracy, to have been the seat of the initial active lesion of its commencement. Lewis has traced the descending degeneration as far as the sciatic nerve, and Westphal and others have described ascending degeneration from lesions of the spinal cord, traumatic and others, while some recent observers think that some cases at least have the origin ascribed to the disease by Messrs. Poincaré and Bonnet, who, in 1863, found marked changes in the sympathetic ganglia, and considered them primary.

As this paper is not designed for those who have given special attention to nervous diseases, I will venture to recall the variety of symptoms likely to be present, and I will enumerate them as nearly as possible in what I believe to be their order of frequency. It is a disease always presenting during its course both motor and mental symptoms, which, however, may vary greatly in their character, intensity, and order of appearance. The motor symptoms are always evidences of diminished muscular power or control, and may affect any muscles, but usually do appear first in those groups whose functions require the greatest harmony and nicest adjustment in action. Hence the common early motor symptoms are defective articulation, tremor of the tongue, tremor of the facial muscles when expressing emotion, irregular chirography, inability to control the hands in such nice movements as are requisite in playing musical instruments, general tremor, incoördination or paretic weakness of gait, and occasionally localized chronic spasms, most frequent in the face. Perhaps, too, the seizures which occur sometimes during the history of most cases may best be included with the motor symptoms. These may occur at any time, and may simulate petit mal, grand mal, apoplexy, or have a mixed character peculiarly their own.

Of sensory symptoms there may be dysæsthesia, hyperæsthesia, anæsthesia, and, exceptionally, almost any variety of neuralgia.

My experience leads me to regard disorder of the special senses as a rare early symptom, and not very frequent later one, but both impaired function and hallucinations of all are reported.

To the sympathetic system, probably, may properly be charged most of the pupillary changes, which are, inequality, usually shown most strikingly by the failure of one pupil to dilate as readily as the other in moderate light; a marked decrease in the size of both, making sometimes the pin-hole pupil, and sluggishness in action in varying light, in accommodation, and in answer to sensory stimuli. To the vaso-motor control of the sympathetic must also, I think, be ascribed the irregularities in the superficial circulation frequently shown by localized or general flushings, resembling

that seen in one accustomed to alcoholics when slightly under their influence. There are other symptoms which cannot well be classified pathologically, but which possess some value for diagnostic purposes, as the condition of the tendon reflex, which may be not noticeably changed, increased, or absent.

Similar changes of increase or diminution may occur in the skin, cremasteric and sphincter reflexes, but are not often seen until later in the disease.

All known mental symptoms are found with greater or less frequency, those usually considered characteristic being a marked feeling of self-complacency and content, and delusions of wealth, greatness, and power.

Eighty-seven of my one hundred cases were men, and thirteen women, but I have not considered them separately, except as regards some mental symptoms which seem modified by sex.

The frequency with which each of the various physical symptoms mentioned appeared as the first physical change is as follows:—

Some defect of articulation thirty-eight times. The text-books often attempt to enumerate various kinds of articulatory defect that occur in general paralysis, but any such classification is rather incomplete and misleading, as any part of the articulatory apparatus may be chiefly affected and all kinds of disorder occasioned thereby. A hesitancy of speech, recognized best when the patient is quietly conversing, and an occasional elision of a syllable, best recognized when the patient is earnestly conversing, are probably most frequent.

Some form of seizure appeared first twenty times. Thirteen of these seizures resembled closely the convulsions of grand mal, the patient falling to the ground and being generally convulsed, but none of them are known to have given the epileptic cry, and the succeeding coma or stupor was much more pronounced and prolonged than in ordinary epilepsy. Four of this thirteen were sent to the hospital diagnosticated simply as cases of epilepsy.

Four of the seizures resembled petit mal, the patients losing consciousness, but having no noticeable convulsion. Three were considered apoplectic attacks and resembled apoplexy in that the patient fell, and remained completely or partially comatose for a time, with little or no convulsive movement. My cases indicate that seizures should have greater prominence as early symptoms than is given them by most authors, but I am unable to say whether they are exceptional in this respect or not.

Tremor of the lips and face was noticed first eight times.

Incoördination of gait, ten times.

Diminished sexual power, six times.

General tremor, six times.

Cutaneous numbness and tingling, three times.

Changed chirography, two times.

Dilatation of superficial capillaries and sensations of heat, once.

Dilatation of superficial capillaries and marked hyperidrosis, once. (I have seen this same marked hyperidrosis in one other case as a later symptom.)

Localized cutaneous hyperæsthesia, once.

General cutaneous hyperæsthesia, once.

Ptosis, external strabismus, and diplopia, once in a syphilitic case.

Diplopia alone, once in a syphilitic case.

Failure of sight from atrophy of the optic nerve, once in a syphilitic case.

Nine of these patients also suffered from decided pain and discomfort in the head previous to other symptoms — it being sufficiently marked in four cases to excite suspicion of brain disease.

There are some other symptoms which may have appeared early and escaped notice, as they are of a character not likely to attract the attention of the non-medical observer, and I can only give their relative frequency at the time the patients were admitted to the hospital, which was at varying stages of the disease. Thus the patellar tendon reflex appeared normal in forty-six cases; markedly supra-normal in twenty-four cases; very marked but not necessarily supra-normal in fourteen; very slight but not necessarily below normal in twelve; absent in four.

The number of cases in which it was found supra-normal is comparatively greater, and the number in which it was found slight or absent less, than in those observed by Mickle in England and Westphal in Germany, but corresponds pretty closely with Shaw's observation in this country.

My whole experience, which extends over a larger number of cases than the one hundred mentioned, agrees with the ratios of their figures as to patellar tendon reflex, and my estimate of its usefulness in diagnosis is as follows: The absence of change does not render the disease improbable.

Well-marked exaggeration in both legs is strong corroborative evidence of general paralysis. Diminution or absence of it is decidedly less so, but still has some value.

There has always been disordered gait in the cases where I have seen it absent; and I have no doubt tabetic lesion of the cord.

I carefully observed the length of duration of the disease at the time when the examination of the knee jerk was made, but there was no indication of a connection of particular conditions with different stages.

On admission the size of the pupils was unequal in sixteen of my cases, the right being larger in ten, and the left in six. Both pupils were abnormally small in six cases, and both dilated in four. None of these changes seemed more frequent at one stage of the disease than at another.

These figures indicate that inequality of the pupils is not very common, and my own opinion, based on the examination of other cases, in addition to these, is that its diagnostic importance is usually overrated by the text-books, as its absence has no significance and its presence may be the result of several causes other than general paralysis.

The mental change which appeared first most frequently was failure of capacity. This was true of thirty-six cases, it being chiefly noticeable in nineteen, because of impaired power of memory, and I will venture to remind you that, as this failure is most frequently due to lessened power of attention, the examination should not be concerning events occurring long ago when there was presumably mental integrity, but concerning trivial matters of recent occurrence. Dr. Holmes makes his old man testily refute this imputation of failing memory by saying: "I remember my great-grandma! She's been dead these sixty years."

And many a general paralytic can give you an accurate history of the events of his previous life long past, when he is unable to tell you where he dined day before yesterday. It is also true that the memory will occasionally assist the patient to conceal failure of

reasoning power, as in the case mentioned by Mendel, where the patient answered readily and correctly that twelve times twelve is one hundred and forty-four, but made twelve times thirteen a less number.

In eleven cases the mental failure was evinced by poor judgment in business, without manifest change in activity or habits of life, and in six cases this entailed serious financial reverses on the patient and his family.

In the remaining six cases of mental failure it appeared simply in mental sluggishness, great and unaccustomed disinclination for mental or physical exertion, accompanied in three cases by a striking tendency to sleep.

Marked depression without obvious delusion was noticed first twenty-two times. Marked exhilaration and self-satisfaction, seventeen times. This was accompanied by erotism in nine cases, two of them attempting rape, two indecent familiarities and exposure, and three began an unusual and scandalous course of licentiousness. Several others of this class, before abstemious, became addicted to alcoholic excesses, and attention was attracted to two by thefts which were undoubtedly the outcome of the disease, though not so recognized until the courts had taken action in both cases and one of the men was in prison.

Insane delusions were noticed first twenty-five times. They were the characteristic ones of wealth and greatness, in twelve cases.

Six showed a variety of delusions of persecution; six believed their wives unfaithful, probably chiefly because their erotic desires met repulse, and were dangerous to them thereby; and one had general delusions, based on hallucinations of hearing.

Maniacal excitement, of extreme intensity, sometimes appeared very rarely in fifteen cases, but was not the first symptom noticed.

The thirteen women exhibited no marked variation from the men in physical symptoms, but the mental symptoms were commonly much less pronounced and active.

Six showed simple dementia. Three had definite delusions that men outraged them; and two, delusion that some spirit or angel had sexual intercourse with them.

Two had ordinary delusions of persecution. Several of those who had delusions of being outraged thought themselves pregnant; and this is, by some observers, considered a frequent delusion among female general paralytics. I think that the delusions as to sexual intercourse usually depend on the misinterpretation of an orgasm, experienced at night; and those of pregnancy, indirectly on the same, or on anomalous sensations in the abdomen.

Three of these women were of very good social position, and this is a larger proportion than is found abroad, where general paralysis is considered very rare among those having the social rank of ladies.

The relative time of appearance of the two classes of symptoms was as follows: In sixty-eight cases the mental and motor symptoms were noticed at the same time.

In twenty-four, mental symptoms alone first attracted attention; and in eight, the motor symptoms.

These figures are undoubtedly inaccurate, as slight changes, particularly of a motor character, might readily escape the notice of a non-expert observer, and some motor changes would unquestionably have been observed by an expert in many of the twenty-four cases

which are recorded as presenting mental symptoms alone at first, but they do show that much difference of time between the appearance of the two classes of symptoms is exceptional, though it is true that either may show remissions or intermissions early in the disease, so that their existence can only be learned by careful questioning as to the previous history. Thus, one may see a patient laboring under intense maniacal excitement, in whom no motor paresis can be detected, but who has a history of previous convulsive seizures, or attacks of unconsciousness, which change the diagnosis from curable mania to general paralysis. In one of my cases, a woman, marked defect of articulation was for some time regularly present each morning, but disappeared before noon, and it is not at all uncommon to see pronounced symptoms of any kind diminish greatly or disappear if the patient is changed from excitement and dissipation to a quiet routine of life.

In the few cases where mental symptoms appeared to me to unquestionably precede the physical, they were almost invariably those of marked depression not reaching the grade of positive insanity, and the physical symptom that appeared alone first most frequently was some form of seizure.

Finally, the symptoms presented by these cases appear to me to indicate, with the somewhat moderate weight of authority to which their numbers entitle them:—

(1.) That the striking and characteristic group of symptoms ascribed to the disease by Calmeil in 1826, and having greatest prominence in most text-books since, is to be found only exceptionally in the cases of to-day at the time when the diagnosis is the most important.

(2.) That physical and mental symptoms usually appear nearly synchronously, so that the physician has the presence or history of both to aid him when called upon for a diagnosis, and it is probable that most of those who report cases of general paralysis without mental impairment are not sufficiently expert to recognize a moderate degree of dementia.

(3.) That their observations agree with those of most writers in making defective articulation the most frequent and characteristic early motor symptom.

(4.) That changes in the pupils and disorders of gait are less frequent and have less value in diagnosis than is usually ascribed to them, and that given pupillary changes are no more frequent in one stage of the disease than in another.

(5.) That the patellar tendon reflex is found markedly supra-normal in nearly twenty-five per cent. of general paralytics, and that the presence of this symptom has strong corroborative value in diagnosis, though its absence has none, and that no peculiar condition of the patellar tendon reflex can be associated with any given stage of the disease.

(6.) That hallucination or impaired function of the special senses is very rare as an early symptom; hallucination (auditory) having been noticed first in but one case, and impaired vision but once in a syphilitic case. The diminution in the sense of smell, which Voisin thinks very frequent in the early stages, was not noticed in any of my cases, though it may have been present and escaped attention in some, as slight failure is difficult to recognize.

(7.) That it is of great importance in the case of a patient showing mental symptoms to inquire carefully

for a history of convulsions or loss of consciousness, as these were the first motor symptom in twenty of my cases.

(8.) That among mental symptoms the marked exhilaration, with delusions of wealth and greatness, which is usually considered the characteristic mental symptom, is present early in less than one fourth of the cases, and that simple failure of mental capacity and activity and mental depression are the more frequent first mental changes.

THE REMOVAL OF FOREIGN BODIES FROM THE HUMAN BLADDER BY A NEW INSTRUMENT.

BY JOHN W. MERRILL, JR., M. D., WEST SOMERVILLE, MASS.,
Fellow of the New Hampshire Medical Society.

CASE of Mr. H., aged thirty-five years, white, a native of Boston, by occupation a traveling salesman.

In September, 1880, he contracted gonorrhœa, and as a result of bad treatment and improper habits had a stricture situated four and a quarter inches from the meatus. He had difficulty in passing urine, and retained it at times until the bladder became distended and painful. His general condition became lowered, with loss of flesh, also with chills, fever, and profuse sweating. At this stage, ten months after contracting his disease, he consulted Dr. —, of Boston, who passed a catheter, and then sounds of increasing sizes up to a No. 20 F. He left the city somewhat improved.

In August, 1881, he returned to Boston in a bad condition, with all the symptoms as before stated, that is, chills, sweatings, and retention. He had neglected to pass sounds in the mean time. He called on Dr. —, who, to relieve him, passed with difficulty a No. 8 English catheter (after trying to pass a sound of larger size). This was forced through the stricture into the bladder, the distended bladder was emptied, and, on attempting to withdraw the catheter, it was found that the stricture had grasped it so tightly that it could not be removed. The doctor waited ten minutes for the spasm to pass off, and then gave the catheter a quick jerk, when lo! he held part in his hand and the remainder was in the urethra and bladder. The catheter had broken. After half an hour's useless endeavor to grasp the catheter with a long pair of forceps, he at the patient's request passed a sound and pushed it back into the bladder. The patient, with many oaths, would not submit to any further attempt to remove it, and left the doctor.

In September I made his acquaintance. He had the following symptoms: cystitis, frequent and painful micturition, pain at the meatus of the penis, pain in the region of the kidneys, and on passing a No. 16 F. steel sound I could feel the foreign body, and could get the click as the steel sound hit the incrustated catheter. I recommended that he have the urethra dilated by sounds gradually to a size sufficiently large to admit the passage of a No. 32 F. steel sound, and then pass in an instrument, grasp the catheter, and extract it. To this he agreed. The sounds were passed in Boston by my esteemed friend Mr. Charles Kelly, a medical student, until a No. 32 had been passed once every four or five days, and left

in fifteen to twenty minutes at a time. Perineal hypodermic injections of Magendie's solution of morphia were given him ten minutes before passing the second sound, when necessary, which controlled in a great measure the spasms of the urethra; two sounds were passed at a sitting. At times the piece of catheter would get into the prostate, but would not pass out. Injections of tepid water and morphia were repeatedly used without avail. It would get a certain distance and then cause the most intolerable pain and anguish, and the only way relief could be obtained was to pass a sound and push it back into the bladder.

I had in the mean time an instrument made, as per drawing, composed of a hollow sheath or catheter-tube,

having male and female blades, which can be opened and closed, and an extractor provided with gripping-claws adapted for insertion and operation within said sheath, in a manner hereinafter explained.

The sheath, A, is constructed of suitable metal, formed as a hollow tube, having the general shape of urethral sound or catheter, with a short curve at its entering end, which is properly and smoothly rounded, as shown. The sheath is formed of two parts, grooved together at their edges along the straight portion, so that the male part, A', can move longitudinally in the part B, for opening or closing the male and female blades, *a b*, which comprise the curved portion of the tube. Said blades, *a* and *b*, are both made hollow or concaved on their inner sides, the cavities being of sufficient size to receive and cover the jaws of the extractor, C, which is inserted and withdrawn through the sheath or catheter-tube as required. A ring or other suitable handle, *d*, is fixed on the outer end of the sheath for steadying and guiding the instrument when in use, while a suitable thumb-piece, *e*, is fixed on the shank of the male blade, A, for effecting the movement of said blade as desired.

The extractor, C, consists of a shaft or rod of convenient length and size to pass through the sheath, one end thereof being provided with a suitable handle or ring, *d*, while to its other end are hinged or pivoted, as at I, two claws or hooked grippers, F and H, the ends of which are curved toward each other and provided with sharp points, N, or with a series of serrations or pointed teeth. The form and size of these claws are such that they can be inclosed within the cavities of the blades, *a* and *b*, of the sheath A, or be drawn through the tube by means of the shaft C. A spring, G, is provided for forcing apart the claws, F and H, which spring is connected to one of said claws and arranged for pressing against the other as indicated.

An auxiliary shaft or rod is arranged along the shaft, running parallel therewith, and guided by bands C' or otherwise. One end of said auxiliary shaft is connected by a suitable link, L, to claw H, as indicated at M, while its opposite end is turned upward at a right angle, as at K, to form a handle or thumb-piece by which the shaft and claw can be actuated, and the claw H be closed against the claw F for gripping any substance that may come between them. The claws can

also be closed together by withdrawing the extractor shaft from the sheath.

Near the handle end of the extractor is a pin or lug, J, which is adapted to engage with a slot, O, formed in the end of the sheath to prevent the extractor from revolving within the sheath, or for retaining the claws, F and H, centrally within the hollows of the blades A and B. The claws can be made to have any suitable curvature and form of gripping points. By making the male and female blades with inner cavities, as shown, the claws are allowed space to pass around the substance or body which may lie between or be clasped by the blades. The blades may be made of sufficient strength and stiffness to crush moderately hard substances, although the instrument is not intended for crushing purposes.

By appointment Mr. H. came to Concord, N. H. (where I was then practicing), March 13, 1882, for operation. I gave him a large dose of bromide of quinia and aromatic sulphuric acid. I stood him up against the wall, and passed the instrument into the bladder, felt the foreign body, then drawing out the male blade grasped the piece of catheter between the lips, and, revolving it half way, passed down the extractor and seized the body; I then drew the male blade further out to keep back the mucous membrane of the bladder, and made traction on the extractor, and with force drew the piece of catheter out of the bladder through the instrument. It proved to be four and a half inches long. I closed the male blade against the female blade, rotating it to be sure none of the bladder wall was engaged in the lips, and then slowly withdrew it. A few drops of blood flowed, due to the size of the instrument. The operation lasted ten or fifteen minutes. He walked out of my office in half an hour after entering. No chills followed the operation. All inflammation has passed away, and he is now well.

On examining the piece of catheter on and in it I find a deposit of uric acid, oxalate of lime, phosphate of lime, triple phosphate; uric acid crystals seem to be the most abundant; the triple phosphate next. The weight of the deposit was thirty-eight and a half grains.

REPORT ON PROGRESS IN THE TREATMENT OF DISEASES OF THE THROAT.¹

BY F. I. KNIGHT, M. D.

ON THE TREATMENT OF CHRONIC GRANULAR PHARYNGITIS BY THE GALVANO-CAUSTIC METHOD.

DR. GEORGE MACKERN, of Buenos Ayres,² says his apology for recording cases of such a common disease is, first, that they are cases of an advanced and severe type with certain peculiarities which he had not observed in London; second, the comparatively recent introduction of the galvano-caustic method of treatment; third, the fact of their being cases occurring in a country the climatic and hygienic peculiarities of which might possibly exercise some influence over the forms in which the affection manifests itself; fourth, the well-known chronicity and obstinacy of a disease which has hitherto resisted all ordinary modes of treatment. Case II. was in some respects the most

¹ Concluded from page 153.

² Archives of Laryngology, January 1, 1883.

satisfactory of all. The number of granules actually destroyed by the galvano-caustic formed but a small proportion of the number which existed at the beginning, but after each application a certain number of untouched granules would disappear. Dr. Mackern thinks this must be due to the destruction of the blood-vessels in connection with them, the process in this case being analogous to the rapid disappearance of torpid granulations in chronic ulcers when their edges are incised, where not only is the tension of the surrounding skin relieved, but a sort of local bleeding and consequent diminution in the engorgement is also to be considered.

The cause of the elongated and flabby state of the uvula in Case III. was considered to be the presence of the inflamed glands at its base producing inflammatory paralysis of the azygos uvulæ muscles; when the glands were destroyed the uvula regained its normal shape and irritability.

Several cases came under the author's observation showing marked venous vascularity of the pharynx with tracts of softened granular material. In many cases, too, the mucous membrane around these tracts was swollen and oedematous looking. All these were old-standing cases, and their chronicity forms an important factor in the ætiology. The author says that the presence of these softened masses can be explained as follows: Each granule in ordinary granular pharyngitis is connected with a minute branch of a vein whose main trunk is connected with certain areas, and the presence of the venous supply he believes to be secondary to the glandular hypertrophy, and due to it. The disease being neglected the glands continue to hypertrophy, neighboring ones coalesce and form the larger masses and tracts so common in advanced cases. *Pari passu* with this also increases the venous supply; hence the existence of the large, thin-walled veins. Degeneration of the gland cells takes place, and the masses soften down in the centre; hence the presence of the so-called "varicosities." Therefore Dr. Mackern has no hesitation in burning these large, softened masses, and as yet this method has proved efficacious without any evil result. As a rule, these larger masses require a second and even a third touch of the cautery, but they eventually disappear, and with them the abnormal venous supply. As regards the ætiology of granular pharyngitis three causes appear to the author to warrant more attention in connection with the disease in Buenos Ayres, namely, heredity, exposure to damp, and tobacco smoking.

Concerning the use of the galvano-caustic method the author says he has been uniformly pleased with the results in a great number of cases. Although apparently a severe measure no evil results have ever followed its use; it is convenient, painless, and cleanly, in fact it seems to be antiseptic, as the sloughing is uniformly followed by rapid and healthy healing.

THE PATHOLOGY AND RADICAL CURE OF HAY FEVER OR HAY ASTHMA.

Dr. Roe, of Rochester, read a paper on this subject before the Medical Society of the State of New York, February 6th.¹

Dr. Roe begins his paper by referring to the want of positive knowledge in regard to the nature of the disease, and the unsatisfactory character of its treatment. In this connection he says that in the works

on this subject we find usually no mention of any examination into the objective condition of the nasal passages, nor of any investigation as to the existence of any localized diseased condition which may predispose to the affection.

Dr. Roe claims that recent investigations show that the special cause for hay fever does not alone reside in a special peculiarity of a special irritant, which affects certain individuals in a peculiar manner, but in a special susceptibility of the tissue of the nasal passages of some individuals to be irritated by these substances when brought in contact with it; that this susceptibility of this tissue is occasioned by disease either latent or active; that the removal of this diseased tissue will remove the susceptibility to irritation by these substances; and that the train of symptoms, which appear to be more or less of a constitutional nature, producing the asthmatic and nervous symptoms (which have led to the classification of the affection as a neurosis), is but the result of the irritation of the Schneiderian mucous membrane, which is reflected to other parts and organs through the agency of the sympathetic nervous system, causing irritation in these organs, which is augmented by the consequent obstruction to nasal respiration during the attack.

Covering the inferior turbinated bones and the lower part of the septum there is a highly vascular erectile tissue analogous to the cavernous tissue of the genital organs (Bigelow). This vascular erectile tissue is directly under the control of the vaso-motor nerves, and is exceedingly sensitive to impressions applied not only locally to the part, but to other portions of the body. Often it may be noticed that a draft of cold air striking another portion of the body will cause this tissue to become engorged sufficiently to occlude one or sometimes both nostrils.

Sometimes slight disease or hypertrophy of this tissue, and not sufficient to give the patient any special annoyance, will increase its susceptibility to irritation to a marked degree, and it is the irritation reflected from this tissue, through the sympathetic nerves to other parts and organs, which is the excitor of the varied and distressing symptoms complained of by hay-fever sufferers.

It is proved by experiments on animals that violent irritation of the Schneiderian mucous membrane will induce, through the sympathetic nerves, congestion and irritation in the larynx and lungs similar, though in a less degree, to the derangements induced in the lungs by irritation of the larynx. The conclusion that hyperæsthetic tissue of the nasal passages sustains a certain relation to the causation of hay fever has been reached in a natural manner by observing from time to time that patients who were under treatment for nasal diseases, and who also suffered severely from hay fever during the summer months, were relieved, or their attacks lessened in severity, in proportion as these diseased conditions in the nasal passages were removed; and that in cases where this hypertrophied turbinated tissue was removed altogether, the patient became entirely exempt from subsequent attacks.

It has been observed, furthermore, that in every instance in those who were subject to hay fever, more or less disease or hypertrophy of this tissue existed.

For treatment Dr. Roe recommends the removal of the hypertrophied tissue with galvano-cautery or the Jarvis' snare. For galvano-cautery a small elec-

¹ D. Appleton & Co. 1883.

trode is recommended, burning but little at each introduction. Vaseline warmed and thrown into the nostrils with a spray tube immediately after the operation, and until the slough separates and the parts are healed, will almost invariably prevent inflammatory complications. Aqueous solutions for spray should not be used.

NASAL COUGH AND THE EXISTENCE OF A SENSITIVE REFLEX AREA IN THE NOSE.

Dr. John N. MacKenzie¹ concludes :—

(1.) That in the nose there exists a definite, well-defined sensitive area, whose stimulation, either through a local pathological process or through the action of an irritant introduced from without, is capable of producing an excitation, which finds its expression in a reflex act, or in a series of reflected phenomena.

(2.) That this sensitive area corresponds, in all probability, with that portion of the nasal mucous membrane which covers the turbinated corpora cavernosa.

(3.) That reflex cough is produced only by stimulation of this area, and is only exceptionally evoked when the irritant is applied to other portions of the nasal mucous membrane.

(4.) That all parts of this area are not equally capable of generating the reflex act, the most sensitive spot being probably represented by that portion of the membrane which clothes the posterior extremities of the inferior turbinated body and that of the septum immediately opposite.

(5.) That the tendency to reflex action varies in different individuals, and is probably dependent upon the varying degree of excitability of the erectile tissue. In some the slightest touch is sufficient to excite it, in others chronic hyperæmia or hypertrophy of the cavernous bodies seems to evoke it by constant irritation of the reflex centres, as occurs in similar conditions of other erectile organs, as, for example, the clitoris.

(6.) That this exaggerated or disordered functional activity of the area may possibly throw some light on the physiological destiny of the erectile bodies. Among other properties which they possess may they not act as sentinels to guard the lower air-passages and pharynx against the entrance of foreign bodies, noxious exhalations, and other injurious agents to which they might otherwise be exposed?

Hospital Practice and Clinical Memoranda.

CARNEY HOSPITAL.

SERVICE OF DR. G. M. GARLAND.

PEMPHIGUS PRURIGINOSUS.

THE following case is of interest on account of the rarity of the disease, and because of the mental disturbance which accompanied it:—

November 22, 1881. J. N., a widower, seventy-eight years of age, and a ship carpenter by trade, has always been a hale, hearty man until recently, when he has become weak and prostrated by the disease for which he enters the hospital. About three years ago he noticed small water blisters over the lower part of the sternum, and extending to either side of the same.

¹ American Journal of the Medical Sciences, July, 1883.

The blisters broke and left open sores, which in turn healed slowly. As one blister disappeared, however, another came, so that during this three years the region specified has never been entirely healed.

About ten weeks ago similar blisters appeared on his legs, and from there the eruption spread to his thighs and arms, and was accompanied with great *itching* and *burning*. Patient says he has lost strength and flesh rapidly since this last eruption, and can hardly sleep for the itching. Appetite was good. Urine normal in amount, and also on examination.

Exposure of his body revealed a remarkable state of the skin. His legs and arms were covered with blisters, raw surfaces, and deeply pigmented cicatrices of former blisters.

The blisters varied in size from a pea to an English walnut. They were filled with a straw-colored fluid, and were so tense that on pricking the covering the fluid would spurt out with force. The raw surfaces varied also in size, and were dark red, with a slimy secretion over them. The pigmented spots were very dark colored, and when the patient stood erect those on his legs became purplish. Wherever the intact skin admitted of scratching it was covered with finger-nail excoriations, testifying to the suffering of the victim from itching.

Counting blisters and ulcers, and including a few extra ones which appeared after the patient entered the hospital, his score stood as follows:—

Right leg	75 ulcers.
Left leg	80 ulcers.
Right arm	50 ulcers.
Left arm	45 ulcers.
Front of chest	30 ulcers.
	<hr/>
	280 ulcers.

It will be noticed that the eruption was confined to the legs, arms, and front of chest. At this time the patient's mind appeared clear and rational in every respect. The patient was put on a generous diet, with quinine, and ordered to keep his bed. To protect the clothing from the copious secretion from the sores the affected parts were bathed in a solution of carbolic acid, and then enveloped in large sheets of oiled silk.

The patient, protected from the discharge and resting in bed, was more comfortable, but otherwise no improvement appeared for several days, and new blisters came out. Then the following dressing was adopted morning and night: the sores were carefully and thoroughly cleansed with carbolic wash, and wiped dry; then each sore was dusted with iodoform powder; loose cloths and the oiled silk wrappers were lightly tied around the parts.

December 2d. Patient doing well. The eruption more than half healed.

December 11th. The sores continued to heal satisfactorily, but patient began to show signs of insanity. These symptoms continued to grow worse until December 16th, when he was wild all day and continued in that condition for several days. Patient did not know where he was; tried to escape from the hospital; could not be kept in bed. Five minutes after a hearty meal he would declare that he had had nothing to eat and thought we wanted to starve him. At times he would recognize his physicians and attendants, but at his worst he did not know anybody, and was pugnacious. He tore off his dressings, and finally was removed to a private room with an attendant.

December 17th. Dressings discontinued. Ulcers nearly all healed.

December 18th. Gave bromide of soda in frequent doses.

December 20th. Ulcers reported *all healed*.

December 21st. Appears more rational.

December 23d, 24th. Recurrence of insane symptoms. Threatened his own life.

From this time on he began to improve mentally until January 2, 1882, when he was discharged well.

This was a typical case of pemphigus pruriginosus, which Hebra declares incurable and always fatal. The treatment consisted of rest, in the horizontal position, small doses of quinine, good diet, cleanliness, carbolic wash, and iodoform powder. The rapid improvement in the appearance of the ulcers after the application of the iodoform was noticeable to all who watched the case. Moreover, it was also remarked that *new blisters* ceased to form after the application of the powder, and as we know that iodoform is readily absorbed by raw surfaces, the question arises as to how far the constitutional effect of the absorbed iodoform contributed to this happy result. About a year after treating the above case I noticed a similar case reported by an English physician, which was treated with Fowler's solution, and the reporter of the case claimed that this solution is an infallible remedy for pemphigus.

The success of my own case would indicate that we also have a very reliable remedy in iodoform.

Medical and Surgical Journal.

THURSDAY, AUGUST 23, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

CHARITY HOSPITAL, NEW YORK.

In a carefully prepared article the *New York Times* has recently invited public attention to the present excellent condition of Charity Hospital, Blackwell's Island, New York. While fully recognizing the ability of the visiting and resident medical staff, it attributes this in great measure, and apparently with justice, to the marked efficiency of the corps of trained nurses, which is the special pride of the institution, and which will undoubtedly compare favorably with any similar body in the country. In connection with this point it speaks of the very unsatisfactory state of affairs as revealed by public investigation, which has for some time existed at Blockley Hospital, the corresponding institution in Philadelphia, and in consequence of which, not long since, a committee of officials and prominent citizens of the latter city came over to New York for the special purpose of inspecting the system of internal administration carried out at Charity and other hospitals. In 1883, while the death-rate at the Philadelphia Hospital, whose nurses are

described as for the most part ignorant convalescent paupers, was 9.59 per cent., at Charity Hospital it was only 6.06 per cent. While this great difference may be due in part to other causes, there can be little doubt that it is mainly attributable to the superiority of the trained nurses in the latter institution.

One circumstance which must have a very favorable effect on the mortality of Charity Hospital is its admirable situation near the southern extremity of Blackwell's Island, where, with the rushing tide of salt water on either side of the narrow point on which it stands, there is always an invigorating breeze, and as most of the wards have three exposures the most perfect ventilation can be secured. The day that the representative of the *Times* visited the institution the thermometer in the city, directly opposite Blackwell's Island, indicated 92° F. in the shade, while at the hospital at the same hour it registered only 86° F.

There are over a thousand beds in the hospital, and it is rare that any of them are vacant. During the past year 8028 patients were admitted, and of these 530, or 6.06 per cent., died, quite a large part of the mortality being due to phthisis. Of the admissions 4762 were males, and 3206 females; 3096 were natives, and 4932 of foreign birth. In the maternity department the statistics are extremely gratifying. The number of births during the year was 423, and the number of deaths from puerperal causes six, or less than one and one half per cent., while in 1876, with about the same number of confinements, the deaths reached thirty-six. Considering the class of patients that are received into the obstetric wards of such an institution, this is certainly an excellent showing, and affords a marked contrast to the state of affairs in Blockley Hospital, where the mortality among the puerperal patients during the last year is said to have been something frightful. The number of cases delivered by forceps was twenty-five, and with reference to this point Dr. Leaman, the chief of staff of the hospital, says, in his annual report, "The small number of cases where instruments were used, compared with the whole number of patients, is very significant. The process of maternity is so natural and unvarying, in spite of all possible complications, that the law of non-interference may almost be called one of nature's own making."

The large building standing on the extreme point of the island, south of the main hospital, known as the Riverside Hospital, and of late years used for small-pox patients (who will in the future be taken to the new hospital buildings on North Brother's Island in the harbor), will shortly be vacated, and turned over to the Commissioners of Charities for the use of the Training School for Nurses. The school will thus be provided with the most commodious building of any in the United States, or, probably, the world, while the capacity and efficiency of the hospital will be increased, the apartments now occupied by the nurses (which for the most part are immediately adjoining the different wards), being in the future reserved for special medical and surgical cases likely to be benefited by isolation. A long-felt want will thereby be

supplied in the hospital. Another improvement which has lately been inaugurated by the hospital authorities in their efforts to raise the standard of the institution is the exclusion from its wards of the sick from the work-house and other penal institutions on Blackwell's Island. These are now being provided with hospitals for such of their own inmates as require medical treatment.

FIFTY-FIRST ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION.

THE fifty-first annual meeting of the British Medical Association was held July 31st and the three following days. The place of meeting this year was Liverpool. The attendance was large, the addresses of fully average interest, and the discussions at the meetings devoted to general business were of an unusually lively, we might fairly say very stormy, character, which tried the patience and parliamentary tact of the presiding officer greatly. An abstract from advance sheets of the address in surgery by Dr. Harrison, of Liverpool, was given our readers three weeks ago, and the last issue of the JOURNAL contained a letter from a correspondent on the spot. The address of the president-elect, Dr. Waters, was a sturdy, cheery, characteristically English production. Dr. Creighton, in the address on pathology, took up for consideration the subject of the specific infections without contributing anything particularly novel or acceptable toward the elucidation of present vexed questions.

The Association continues to grow in strength numerically and financially, and if hearty differences of opinion on various questions of internal regulation is a measure of life and vigor, then is it growing in these respects also.

Belfast will be the place of meeting in 1884, and Dr. Cuming, of that place, was named president-elect.

TUBERCULOSIS A CENTURY AGO.

IN a late number of the *Berliner klinische Wochenschrift* (June 11, 1883) Dr. J. Uffelmann gives a curious and instructive account of a remarkable phase in the history of the study of tuberculosis dating back exactly one hundred years before the discovery of the bacillus of Koch, which there is now so strong a temptation to regard as the specific germ of the disease.

In the year 1782 the medical councilors of the Central Sanitary Bureau of Naples expressed the opinion that tuberculosis was to be regarded as an especially dangerous contagious disease. This council numbered among its members many of the highest medical authorities of the time. In accordance with the opinion of its councilors, based upon the view of the communicability of tuberculosis which these physicians unqualifiedly entertained, the Sanitary Bureau promulgated an order establishing hygienic measures to be adopted against the spread of this disease. This document bears the official date July 19, 1782. In general the decree is as follows:—

(1.) Every practicing physician is ordered to give immediate notice to the bureau of the appearance of consumption — "*l'ulcera polmonale*" — in any patient under his care. For the omission to give such notification he is liable to a fine of three hundred ducats, and for a second offense to an exile of ten years from his native country. (2.) Poor patients who may be afflicted with this disease are to be brought to a hospital designated for this purpose without delay or ceremony. (3.) The directors of hospitals are to keep the clothes and bed linen belonging to the departments containing phthisical patients entirely separate from those intended for use in other departments of the hospital. (4.) The superintendent of each hospital shall keep an inventory of all articles of clothing belonging to patients affected with tuberculosis, and on the death of such patients shall personally compare the inventory and the effects of the patients, to ascertain that every article is accounted for. Any violation of this regulation is punishable by imprisonment or even the galleys. (5.) All articles not supposed to have been infected are to be at once thoroughly cleansed; those articles supposed to be infected are to be immediately burned or rendered harmless in some other satisfactory manner. (6.) The directors are to thoroughly disinfect any rooms or wards occupied by patients with tuberculosis by means of whitewashing, and painting the floors, ceilings, and walls. The doors and windows are to be removed and burned, and replaced by new. (7.) Newly-erected buildings are not to be occupied as dwellings within one year from the date of their completion. (8.) Heavy penalties are attached to the sale of any article of wearing apparel from the effects of a phthisical patient, and the penalty affects the purchaser as well as the seller.

These unusually rigorous measures, which virtually placed consumption on a plane with the plague, produced, as may well be imagined, the most disastrous results in all classes of society. If the symptoms of tuberculosis appeared in any member of a family, it was looked upon as the greatest earthly misfortune. No amount of money would at length furnish a place of shelter for phthisical patients; the friends of the sufferer were looked upon as carriers of the infection and were sedulously avoided, and entire families thus fell a prey to misery and want. The most outrageous contracts were executed for the renting of dwellings to the sick. Houses in which a patient with phthisis had died could not be sold for want of a purchaser; many of the rich even were plunged into the deepest poverty, and whole families were reduced to beggary.

Dr. Uffelmann quotes De Renzi,¹ who says: "The injury which these unfortunate regulations occasioned and are still perpetuating is truly indescribable." The same writer proceeds to criticise severely the proceedings of the Neapolitan Council, and does not hesitate to boldly assert that they were actuated by entirely mistaken grounds, and consequently arrived at wrong conclusions. De Renzi, however, Dr. Uffelmann thinks, has not accorded entire justice to the opinions of the councilors. The decree was un-

¹ Storia della Medicina in Italia, v., p. 512.

doubtedly the result of clinical experiences of no small value. Even at this early date there was no lack of careful study which, if not absolutely proving the communication of tuberculosis from one parent to the other or from patient to nurse, at least made this appear extremely probable. It was upon these and similar experiences in the lives of these earlier Italian physicians that the regulations of the decree were founded. They were, however, wrong in regarding clothing and furniture as bearers of the contagium. Many of the most distinguished contemporary physicians adopted the views expressed by the Neapolitan Commission, and among them the chief medical officer of Venice, Dr. Paitoni, who induced that government to establish protective regulations in regard to it similar to those of Naples.

In Portugal similar regulations were adopted as in Naples, and in Germany the communicability of tuberculous disease was supported by the observations of writers of weight. The Neapolitan Commission, therefore, by no means stood alone in its theory regarding phthisis.

Regardless of the disastrous effects upon the population, and deaf also to the protest of that portion of the medical profession which did not accept the opinions of the Sanitary Bureau, the Neapolitan government enforced the regulations in regard to tuberculosis with a degree of persistency and severity which has seldom been approached in the administration of law in Italy. It is nevertheless remarkable that notwithstanding this the decree was retained and enforced. In the year 1809 the Sanitary Bureau again asked the opinion of the Medical Council upon the subject of the communicability of tuberculosis; but now the views of the councilors were in no wise alike. The majority could not now support the idea that the disease was contagious; but the older and more notable members of the Council, who constituted the minority, still firmly clung to the opinions expressed by the Council of 1782, and the decree of that year still remained in force. Even as lately as 1848 it was still in existence, and was somewhat rigorously enforced. Since that time it has gradually fallen into disuse, and is now well-nigh forgotten. Uffelmann says that he endeavored, during a visit to Naples in 1880, to gain some information in regard to the manner in which the regulations were carried out, and consulted many most trustworthy and respectable citizens, but found no one who could remember to have observed it in actual practice. It does not appear in the recent code of laws, nor could he find the text of the decree or any official reference thereto.

MEDICAL NOTES.

— It is said that the first edition of a German translation of DaCosta's *Diagnosis* was exhausted in less than nine months from its publication.

— The *Lancet* criticises Sir Henry Thompson's recent lecture on *Fish as Food*, saying that while it was an able summary of the known facts about fish, Sir Henry went too far in his denunciation of the notion

that fish eating increases brain power as a "complete fallacy." It adds: "It has long been perfectly well known to physiologists that the phosphorus theory must be discarded, but it is a fact beyond dispute that fish is a form of food which is easily digested, and proves specially nutritive to the bodies of brain workers. Sir Henry Thompson thinks that the only way it acts is by putting a man's body into proper relation with the work he has to do. This may be quite true, and doubtless is so, but the brain is an integral part of the body. Moreover, it comprehends a considerable number of the most important centres of the nervous system, whence the body as a whole derives its power. Therefore in putting a man's body in proper relation with his work, fish may chiefly act by supplying his nervous system with specially available nutriment."

— The University of Dublin has granted to Dr. George H. Kidd the honorary degree of *Magister in Arte Obstetriciâ*, an honor which seems to meet with universal approval as being worthily bestowed. The public oration of Professor Webb on the occasion of the conferring of the degree is so felicitous that we quote it:—

"Et nunc mihi, Juno Lucina, fer opem! Ingenio parturienti meo adsis, precor; nam celebrandus adest castus ille sacerdos qui cærimonias ac sacris tuis summa cum religione præesse solet. An me ludit insania poetæ?"

"Continuo audite voces, vagitus et ingens
Infantum —

non infantum, ut in inferis,

"Quos dulcis vitæ exsortes, et ab ubere raptos
Abstulit atra dies —

sed quos favente Junone suâ, ad auras produxit Artis
Obstetriciæ Magister ille noster. Illius natalibus affuit
signum synonymum Hædorum — splendor, ut ferunt,
pluvialis, se quod de Danae referet, pluvialis auro.
Arti Obstetriciæ aliquid debemus omnes. Artis præcipuæ magistrum præcipuum salutemus universi."

— The Grocers' Company of England have offered their first quadrennial discovery prize, amounting to \$5000, for the solution of the following problem, suggested, it is said, by Drs. Burdon Sanderson and George Buchanan, Professor Tyndall, and Mr. John Simon: "To discover a method by which the vaccine contagium may be cultivated apart from the animal body in some medium or media not otherwise zymotic, the method to be such that the contagium may by means of it be multiplied to an indefinite extent in successive generations, and that the product, after any number of such generations, shall (so far as can within the time be tested) prove itself of identical potency with standard vaccine lymph."

— A correspondent of the *Medical News*, writing from Prague, describes the following remarkable crushing injury: "A man's thorax was caught antero-posteriorly between the bumpers of two cars as he was coupling them. Death was instantaneous. At the autopsy no external injury was seen; several ribs on each side were broken, and the heart was found free in the abdominal cavity, it having been torn from its attachment to the great vessels and forced through a

rent which was made in the diaphragm. It is rather difficult to understand how the violence could have acted so as to produce this result; most probably the man must have been stooping slightly forward when caught."

— We understand that the twelve medical men who have been selected for service in Egypt in the cholera districts by the Foreign Office, with the advice and assistance of Sir Joseph Fayrer, will, on arrival, report themselves to Surgeon-General Hunter, M. D., and place themselves under his orders. They will be paid at the rate of £100 per month, with traveling expenses.

— The JOURNAL has given notice previously of the eighth International Medical Congress to be held in Copenhagen in August, 1884. A list of the officers of the Congress are now furnished, consisting for the most part of members of the profession residing either in or near Copenhagen. The organizing committee give notice that in order that the meeting of so many distinguished medical men whom they hope to see on this occasion may be as advantageous as possible, they will, following the example of the later Congresses, communicate with distinguished men of different branches and of different countries in order to prepare a programme. This programme, as well as the rules, will be forwarded to those who are supposed to take an interest in the work of the Congress, and who might be inclined to participate in it. In order that the programme may be ready as soon as possible the committee would be pleased if communications referring to the work of the Congress were sent to the secretary-general before the next 1st of October, so as to be regarded in arranging the definite programme. The programme and rules will be forwarded as soon as possible to every one qualified to participate in the Congress who within the limited time has announced to the secretary-general his interest in the Congress and his eventual intention of participating in it; if possible, also, which section he chiefly intends joining. The secretary-general is Dr. C. Lange, and the president Dr. P. L. Panum, both of Copenhagen.

— A case in which unpleasant effects followed experiments in hypnotism is reported by Bovin. A young lady attending an evening party, after gazing for some time at a shining button, instead of exhibiting the typical hypnotic condition, became unconscious and remained so for an hour. There existed rigidity of the muscles, narrowing of the pupils, respiration of 40, and pulse of 160. The pulse the next day was still at 120. — *Centralblatt für Nervenheilkunde, etc.*

— Erb, as stated by himself at the annual meeting of the neurologists and alienists of Southwest Germany, maintains his well-known views that ninety per cent. of the cases of locomotor ataxia are traceable to syphilis. In the original hundred cases collected by him eighty-eight were syphilitic subjects. These figures and the conclusion drawn from them having been made the subject of wide-spread criticism, and perhaps even of ridicule, it is interesting to note that

in his second hundred Erb finds ninety-one cases of undoubted specific history.

Rumpf, in the same meeting, reports a death from spinal hæmorrhage following nerve stretching in a case of sclerosis. Symptoms directly following the operation seem to place the immediate cause of death beyond a doubt, and in consideration of the questionable results of the operation in such diseases this case comes as a timely warning.

— Mr. Robert Rawlinson, C. E., of England, who has had large personal experience of various cholera epidemics in various countries, writes to the London *Times* regarding the special utility of scavenging as being greater in controlling the disease than any other efforts, including those directed to the water supply. He says: "Scavenging and lime washing, if accomplished in time, appeared to prevent even a commencement of cholera, though it raged in close proximity. The case of Newcastle-upon-Tyne and North Shields in 1864 were notable examples. Dr. Headlam Greenhow, who at the time resided in North Shields, and was chairman of the Board of Guardians, on the appearance of cholera in the north of Europe and at Denmark, at once caused all accumulations of filth to be removed, and all dirty houses, yards, and tenements to be cleansed and lime washed. These things were done about one month before cholera broke out in Newcastle-upon-Tyne, where it was very severe. There was unceasing railway and other road communication between the two towns during the entire period. Cases came from Newcastle and died in North Shields, but not a single case originated in that town. So much for cleansing in time. The water supplied in North Shields was brought in from open reservoirs and old stone quarries, unfiltered, and was so dirty that bags of flannel were tied over the taps to strain the water through as it was drawn. At Bilston, where cholera slew one tenth of the population, and all the excreta was thrown into Bilston brook, a tributary of the river Thames, the water of this river was pumped unfiltered for the supply of Birmingham, but though cholera-smitten patients came into the town and died there, not a single case originated in Birmingham."

He concludes by saying: "The purport of these remarks is, not to say that polluted water may not be dangerous, but to show that as remedial measures with respect to water cannot always at once be carried out, scavenging, that is the removal of visible filth from privies, dust bins, stables, cowsheds, and pig-sties, with washing, cleansing, and lime washing, can be carried out; and if these things are done promptly and effectively there is ample precedent for believing that cholera may be prevented."

— *Science*, alluding to the appointment of Dr. H. Newell Martin, professor of biology in Johns Hopkins University, as Croonian lecturer of the Royal Society of London for the current year, says that the Croonian lecture was founded by Lady Sadlier, in fulfillment of a plan of her former husband, Dr. Croone, one of the founders and the first registrar of the Royal Society. By her will, made in 1701, she devised "one fifth of the clear rent of the King's Head Tavern, in or near Old

Fish Street, London, at the corner of Lambeth Hill, to be vested in the Royal Society, for the support of a lecture and illustrative experiment on local motion." For many years past there has been no formal delivery of the lecture. The council of the Royal Society select from the papers presented to them during the preceding twelve months that one dealing with animal motion which they think most noteworthy, and publish it as the Croonian lecture, sending to the author the sum derived from Lady Sadlier's bequest. The amount of money is trivial, but the appointment as Croonian lecturer is a highly prized distinction. The paper by Professor Martin, which is to be printed as the Croonian lecture for 1883, is on the Effect of Changes of Temperature on the Beat of the Heart. It is interesting to note that the first Croonian lecture delivered by Dr. Stuart in 1738 was on the Motion of the Heart.

— This is how they die from decapitation, according to the scientific but ghastly description of Dr. Holmgren in a communication to the Upsala Medical Society (*Revue Médicale* and *Louisville Medical Times*). The observer was present, and made accurate observations at the beheading of two criminals: —

"Three seconds after the decollation of the first of these the eyes were widely open and the pupils contracted; twenty seconds after they commenced dilating, the dilatation being completed in about two minutes, the pupils afterward remained in a state of medium contraction. Twenty-five seconds after decapitation the eyes turned upward and to the right. Reflex movements commenced after forty-four seconds in little twitchings of the muscles of the neck, after which violent contraction supervened; the mouth was drawn downward and to the left, the tongue also seeming deviated to the left. Some seconds later the mouth, which had been widely open, closed slowly, and then, after some slightly rhythmic movements of the muscles of the face, at one minute and forty-four seconds after the execution, complete repose ensued. From the surface of the section of the neck blood escaped with a hissing sound, and in a jet one metre in length, and thirty-five seconds later there was still an intermittent, jerking discharge of blood. No movement was observed in the body after decapitation. At the second execution Dr. Holmgren was placed so as to observe the eyes during decapitation. At the blow of the axe there was no winking of the eyelids, and the culprit had kept his eyes wide open the whole time his head was on the block. After the head had fallen the same phenomena were observed as in the first case, the jet of blood extending to 1.33 metres. The author concludes from his observations that sensation disappears instantly, and that decapitation is consequently not a very painful operation."

— The case to which allusion was made some months ago in the JOURNAL, in which Mr. Timmins, an English vicar, was indicted for manslaughter, having caused the death of a parishioner by the administration of oil of bitter almonds, which he prescribed in the capacity of an amateur doctor, has recently come to trial, and has resulted in the acquittal of the clergy-

man, as was to be expected, there being no doubt of the kindness of the gentleman's intentions. Mr. Justice Day, however, improved the opportunity to read a severe lesson to the accused on the culpability of a clergyman or any other non-medical person undertaking to give medical advice in a case of serious illness. In this connection we may cite another case of home doctoring reported by a correspondent of a contemporary, where a woman, feeling that she needed a cathartic, took on a Friday two of "Schenck's pills." Not getting the desired effect she took "several" more, the number unknown. Saturday she began to take "Atwood's bitters," and took several tablespoonfuls. Sunday she renewed the attack with seven teaspoonfuls of tincture of rhubarb. Monday morning she wound up with ninety-nine homœopathic pills of unknown brand and strength, but supposed from subsequent history to be arsenicum in a non-Hahnemannian potency. Tuesday she died with symptoms of arsenical poisoning.

— Dr. W. S. Playfair, in a letter to the *British Medical Journal*, denies the insinuation of a critic that massage is merely a freak of fashion in medicine, such as mesmerism and homœopathy have been at previous epochs, and asserts that it is a thoroughly scientific remedy, based on good physiology and common sense, the value of which, in properly selected cases, no one who knows anything of the matter can possibly question, and which doubtless, when improperly applied, is capable of doing much injury, as any other powerful treatment, such as mercury or opium, may under similar conditions. He emphasizes the importance of making a correct diagnosis before employing the agent.

— The permanganate of potash pills recommended by Ringer and Murrell for amenorrhœa have the disadvantage that the common excipients are not available by reason of their rapid oxidation by the permanganate. In solution a dose of permanganate is very nauseous. In a tasteless pill it dissolves slowly, and yet can be easily disintegrated; it is, besides, more agreeable to the stomach than in solution. Mr. Martindale recommends (*Pharmaceutical Journal*, January 13, 1883) as a convenient form for administration in pill: Vaseline two parts; paraffine wax one part; melt; stir till cold, and add kaolin, three parts; mix well. This binds the powdered permanganate together, and with a little dexterity the pills may be rolled out without much difficulty and dusted over with kaolin. They may be coated with sandarach dissolved in absolute alcohol and rendered tasteless. Cacao butter may be used as an excipient, but it in time reduces the permanganate, and it is troublesome to manipulate.

— *Science* makes a quotation from *Arch. de Physiol.*, 1883, 582, concerning the function of the crico-thyroid muscle, which is of interest in connection with the experiments of Drs. F. H. Hooper and H. P. Bowditch (see JOURNAL, vol. cviii., page 521). Martel also brings forward some experiments to show that the crico-thyroid, and not the thyro-arytenoid, muscle is par excellence the muscle used in the production of different tones in singing and speaking. The most in-

interesting point of the paper, perhaps is, that he shows, by registering with simple levers, the movements of the thyroid and cricoid cartilages respectively, that when the different chest-notes (from do^2 to do^4) are sounded the thyroid cartilage remains immovable, while the cricoid is brought closer and closer to it as the pitch of the note is raised. In the contraction of the crico-thyroid muscle, or, as he prefers to call it, the thyro-cricoid muscle, the thyroid cartilage is therefore to be considered as the fixed point. The action of the thyro-arytenoid muscle, according to him, is preparatory to that of the crico-thyroid, in that it gives the vocal cords their proper position, and acts as an antagonist to the latter muscle. The length and tension of the vocal cords, however, are governed by the crico-thyroid. This view of the function of the crico-thyroid is supported by the results obtained when the muscle, or the nerve going to it, is divided in the dog, and, among men, by the pathological cases in which there is paralysis of this muscle. The general result in such cases is a pronounced hoarseness, and an inability to sound any but the lowest tones.

— An exchange calls attention to the value of electricity as an adjuvant to other means for establishing or restoring the secretion of milk in puerperal women. When the secretion is absent or scanty, or when it has been suppressed from any cause, in addition to other modes of treatment (suction of the nipple, poultices of leaves of the *Ricinus communis*, etc.), it is well worth while to employ a weak current of electricity. The mammary gland is to be gently compressed between two electrodes consisting of moistened sponges. A mild current passed twice a day, for from ten to fifteen minutes at a time, will materially increase the functional activity of the gland.

— It seems that the book manufacturers dress the outside of their productions according to the profession for which they are designed. We notice that a publisher announces a new work on medical jurisprudence either in medical sheep or law calf. The basis upon which this natural selection has been founded we are unable to discover. The "cloth" naturally appears to belong to the clergy. We are anxious to see to what variety of books will fall the product of that "new industry" in leather which has been the object of gubernatorial investigation in this State during the past winter. It is to be feared that the aphrodisiac action which has been found to exist in this species of integument may lead to its selection to enhance the dangerous influences of such poems as those of Walt Whitman.

NEW YORK.

— Returns to the Railroad Commissioner's office at Albany show that during the six months ending August 1st 160 persons were killed, and 401 injured on railroads in the State.

— A Mrs. Johnson, the wife of a laboring man on a farm at Tom's River, New Jersey, has just given birth to a third set of triplets. The oldest set are not yet eight years of age, and all the nine children are living and healthy. If it is true, as the Psalmist says, that "happy is the man that hath his quiver full of

them," Mr. Johnson's lot in life ought to be a very enviable one.

— The American Dental Association met in the town hall at Saratoga on the 14th of August, when an address of welcome was made by Dr. W. H. Hall, of Saratoga. The annual address was delivered by the president, Dr. F. G. Clark, of New York.

Correspondence.

SEA-SICKNESS AND BROMIDE OF SODIUM.

MR. EDITOR, — The *New York Medical Record* of July 21st contains a criticism on a recent article of mine in the JOURNAL (July 5th) which should not go unnoticed, if for no other reason than because it involves a total misapprehension of the relation of my views to those of the late Dr. Beard. I am spoken of as arguing against the value of the bromide of sodium, as recommended by Dr. Beard, and am said to ignore the very large number of cases where the bromide does give vast relief.

On the contrary, I merely repeat the opinion already emphatically expressed by Dr. Beard himself as the result of his continued and persistent experimentation and inquiry, when I state that the bromide in small doses is of no value. The following quotation from his work is sufficiently explicit on this point:¹ "The failures that come from the use of the bromides in sea-sickness are the result of these two factors: *First*, the beginning too timidly in doses of ten, fifteen, and twenty grains. This is mere playing with the remedy, and does but little if any good with sea-sickness. Anything short of mild bromization is useless. The dose is not to be considered so much as the effect, — *bromization*. *Secondly*, the waiting until sea-sickness appears before the remedy is given. The bromides are to be taken before we step on board, or before sailing," etc.

Again:² "It is not the bromides but bromization that prevents sea-sickness." "Bromides have been used for I do not know how long, or in how many different ways, for the relief of sea-sickness, but without sufficient success to give great encouragement to those who made the experiments. The bromides as such are powerless to prevent sea-sickness; it is bromization, that is, bromides given in such doses and with such frequency, and pushed so far, as to cause certain symptoms, to which the name bromization is applied, that prevents sea-sickness; and it is to that, and not to the use of bromides, that this work refers."

With regard to the large doses necessary to produce this bromization (Beard places the maximum at ninety grains three times a day), it is not their efficacy that I question, but whether we are justified in giving them for a disease generally of so little real moment, and this is the only point in which I find myself at variance with Dr. Beard. Those writers are far more so who claim results from such doses as ten grains three times a day, and such observers should not be quoted as sustaining Dr. Beard's theory, inasmuch as they are only doing what he terms *playing with the remedy*. For example, the *Record* (July 28th) alludes to Mr. T. M. Kendall, whose experience with 200 patients

¹ A Practical Treatise on Sea-Sickness; its Symptoms, Nature, and Treatment. By George M. Beard, M. D. 1881. Fourth Edition, page 34.

² *Ibid.* Addenda, page 73.

leads him to support Beard's views of the efficacy of the bromide, and that in doses of ten grains. Reference to this experimenter's original article, by the way (*British Medical Journal*, July 7th), shows that his experience was limited to one voyage, during which he had 200 patients on whom he tried a large number of remedies, among which he found the bromide the most efficacious, and in doses of ten grains three times a day. He does not state on how many of these patients he used the bromide, nor at what stage of the voyage, so that as scientific evidence his testimony, besides being totally at variance with that of Dr. Beard, amounts to little in itself. It is just this sort of evidence that should, it seems to me, be looked on with suspicion. Where so many travelers take the bromide it is not surprising that large numbers escape sea-sickness, nor that large numbers recover while taking it, and among them many perhaps who have been sicker on previous voyages, but it must be remembered that this is just the sort of evidence on which quack medicines flourish, and a large amount of it is required to rebut the statements of those who have given the remedy a fair trial with a negative result. Now, as Dr. Beard says, large numbers have tried small doses of the bromide with no effect, and since the appearance of his publication many more have done so under the mistaken idea that they were following his directions, and it is this valuable negative evidence which should not be "ignored" in favor of the enthusiastic statements of more fortunate travelers and physicians. It is the usual custom in scientific medicine to give the *post hoc ergo propter hoc* fallacy a wide berth, and to await repeated evidence and counter-evidence before asserting the potency of a remedy; but it is remarkable to what a degree the custom has been deviated from in this case.

The *Popular Science News*, after an appreciative notice of my article, acknowledges that the bromide in small doses is in the majority of cases useless, but suggests that there are various degrees of susceptibility to sea-sickness, and that the small doses may do something for the slightly susceptible. While this is not impossible, and may be worth the trial, the cure of just such cases should be viewed very critically, for where the susceptibility is so slight that relief appears in a short time after a dose of ten grains of the bromide the suspicion must be strong that relief would have appeared in about the same length of time without medication. . . . Respectfully,

G. L. WALTON, M. D.

Miscellany.

GOOD REMEDIES OUT OF FASHION.

In an address on this subject, delivered at the annual meeting of the Metropolitan Counties Branch of the British Medical Association, by the president, Dr. C. J. Hare, late physician to University College Hospital, the lecturer made a strong plea for a return to the use of certain measures, notably emetics and bleeding, which he admitted were formerly, perhaps, abused, but which he considered in their appropriate cases invaluable. He alludes to practitioners who have never used either of these agents, and proceeds to cite cases from actual experience where such measures are necessary. We quote two from the *British Medical Journal*:

"In suffocative bronchitis the effect of emetics is sometimes magical, and by their administration in such cases not only is immense relief given, but I verily believe—I am certain—that lives are saved. You are called to a patient who has been ill a few days, with increasing dyspnoea; she is sitting up in bed (I draw from nature), for to lie down is impossible; she is restless, and tossing about; the lips, and indeed the whole face, blue; the eyes watery and staring; the pulse quick and small; the cough constant; the expectoration semi-transparent and tenacious; over every square inch of the chest, front and back, from apex to base, you find abundance of rhonchi; moist, sonorous, and sibilant ones in the upper part of the lungs, and muco-crepitant or mucous râles towards the bases. Ammonia and stimulants, right and good in their way perhaps, in such a case are too slow in their action; the patient is, in fact, more or less slowly, more or less rapidly, suffocating. An emetic of twenty-two grains of ipecacuanha in an ounce of water is given; in ten or fifteen minutes the patient vomits, and brings up a huge quantity of that tenacious mucus, and the whole aspect of the case is altered; the distressed countenance is relieved; the breathing is at once quieter; and the patient is able for the first time for the past twenty-four hours to lie moderately low in bed, and to get some sweet, refreshing sleep. The patient is, in fact, rescued from the extremest peril, and in this case, and in many similar ones too, I believe, from otherwise most certain death. Of course, in such cases the emetic is not given for its effect on the stomach, but for its collateral effect in mechanically clearing out the enormous amount of secretion which accumulates in the bronchial tubes, and which the patient is otherwise quite incapable of getting quit of; and thus the half-choking, almost asphyxiated, condition is changed for one of comparative comfort, and time is gained for the action of other appropriate remedies. No doubt the secretion may, and often will, accumulate again; and I have not hesitated again in bad cases to repeat the same good remedy; but it is a fact, and a very positive one too, that, quite contrary to what those who have had no experience in the plan suppose, the system rallies instead of being more depressed under the action of the remedy. . . .

"There is a class of cases in which the right heart is engorged with blood; and in which the only hope of rescuing the patient from death is by bleeding. A man of middle age (I again draw from nature) has considerable chronic bronchitis, with some congestion of the lungs, and, like many other unwise persons, he goes to a southern watering place instead of remaining in his room and in a uniform temperature. Becoming worse, he determines to return home, and travels on a cold spring day; his dyspnoea is so much worse on the journey that his friend and the fellow-passengers doubt whether he will arrive home alive; and when his carriage meets him it is with the greatest difficulty he is conveyed to his house and got into his drawing room. You are at once sent for, the message being that the patient is dying, and when you arrive you find that that is the fact. He is sitting in a chair (to lie down is impossible for him), his face is blue and swollen, his lips purple, the eyes suffused and staring, his heavy, gasping breathing you have only too distinctly heard and recognized as you ascended the stairs, and when you see him you find his chest heaving, and each short gasping inspiration followed by a long

wheezing and moaning expiration; his lungs are full of moist sonorous, and mucous and submucous, rhonchi, and scarcely a trace of vesicular respiration is to be heard, and he is pulseless. He looks to you beseechingly, and gasps out, in scarcely articulate words, that he is dying. This is but too true. Now, the treatment for such a condition at the present day is "to pour in stimulants" (though the patient can scarcely swallow). Brandy and water are given, and ammonia, and perhaps ether; then, if the patient live long enough to have them made, mustard poultices are applied to the chest, and to the calves, and to the feet, and the patient is fanned, and the patient dies. Something has been done, but that which true pathology—and, indeed, common sense, unshackled by prejudice, custom, and fashion—would dictate, has been left undone. Appearances have been saved, but not the patient's life.

"The fact is, that here the danger lay in the right side of the heart being gorged with blood, so that it was impossible for its stretched and distended walls to contract and to propel forwards the thick and blackened blood. . . . Relieve that poor oppressed, distended heart and all may be well! Open one of those veins which are, with every systole of the heart, tending to carry more and more blood to this already distended right ventricle, and all may yet be well with your patient. Sometimes this blood-letting, in extreme cases, is no easy matter; it may be necessary, before you can effectually open the vein, to place the patient's arm in warm water, so as sufficiently to distend the vein; and even when the ligature has been efficiently applied, and the vein well opened, you may have to press and squeeze and rub upwards the arm before a drop of the thick and tarry blood will flow. But, when it *does* flow at length freely, oh, what a marvelous change may you see take place!—the breathing becomes quieter, deeper, and less noisy, the haggard face resumes the appearance of tranquillity, the blueness of the skin is replaced by a more natural tint, the pulse becomes more and more distinct, and, in a word, the choked-up heart is set free. This is no fancy picture. Every word is simple truth, and I appeal for confirmation to the memory of every senior member present who recollects the experience of his earlier days, and who can also probably tell you that the after-progress of such cases was sometimes almost miraculously rapid, so that in a few days even the patient might become convalescent."

EASY METHOD OF POSTERIOR RHINOSCOPY.

DR. W. J. WALSHAM (*Lancet*, July 28th), after pointing out the difficulty in many cases of getting a satisfactory view of the posterior nares on account of the interference of the soft palate, describes a device which in his experience greatly facilitates the manœuvre. While it is in some respects similar to the method suggested by some American surgeons, its author claims some advantages, notably that of requiring no instruments. A piece of soft red-rubber tubing, about one eighth of an inch in diameter, is introduced into one nostril, and pushed very gently along the floor of the nose till it presents just below the soft palate. It is then gently seized with a forceps, drawn out through the mouth, and loosely tied across the upper lip to the end protruding from the nose, the elastic tube being stretched just sufficiently to loop upwards and forwards

the soft palate, and draw it well away from the posterior wall of the pharynx. The looping of the palate on one side is often sufficient; but a better view is obtained by passing a tube through the other nostril and looping up the soft palate of that side in the same way. The posterior nares and naso-pharynx can now be examined with the ordinary laryngoscopic mirror with the greatest facility. One hand only is required to hold and direct the mirror (the stem answering the purpose of a tongue depressor), the other hand is consequently free to perform any manipulation or operation that may be required. The tubes serve as a good guide, as they can be followed in the mirror winding round the upper surface of the palate, and so into the respective choanæ. The introduction of the tube causes hardly any discomfort or annoyance to the patient. Care, however, should be taken in passing the tube to let it only just present below the soft palate, as otherwise, if it is pushed further, it may impinge upon the lower pharynx, and is then apt to produce a tickling sensation and desire to vomit. When the examination is finished it is better to withdraw the tube through the mouth rather than through the nose, and when the nasal end is just about to drop into the pharynx to give it a sharp whisk forwards. If it is withdrawn through the nose the mouth end trails along the tongue, causing a tickling of its posterior part.

The advantages claimed for the red-rubber tubing over tapes and narrow bandages are that it is soft, non-irritating, and possesses just sufficient resistance to enable it to be passed through the nose by itself, thus dispensing altogether with the use of an instrument, the passage of which, as, for instance, in plugging the nares, is, as is well known, a source of much discomfort and annoyance to the patient.

PHYSOMETRA.

THE leading article in the current number of the *American Journal of Obstetrics* is by Dr. H. C. Yarrow, on the above subject. The author first describes a somewhat remarkable case of the disease occurring in his own practice, as follows:—

"In the spring of 1872, the writer was summoned by a physician living a short distance from his place of residence to meet in consultation over a patient considered dangerously ill. In the note which was received no particulars were given, the wording being as follows: 'Meet me in consultation at once, and bring with you such instruments as you may need to perform the Cæsarean operation. No time was lost in obeying the summons, and the patient's dwelling was reached within a brief period. Her medical attendant stated that he believed gastrotomy was imperatively demanded, as she was pregnant, and had gone four months over her time, and as expulsive pains had been felt he feared a rupture of the uterus. The patient was seen, and proved to be a stout negro woman of about forty-six years of age, according to her own statement, and was probably, as she supposed, near the menopause. The patient herself declared she was certain of being with child, as she had borne children before, and was familiar with all the symptoms. She asserted positively that quickening had taken place about the end of the fourth month; her physician was also sure as to her condition, as he had felt the child. An

inspection revealed the abdomen enormously enlarged, the tumor extending far above the umbilicus; there was also considerable lateral enlargement; the breasts seemed full, the nipples pointing. Percussion, however, seemed to negative the other signs of pregnancy, for resonance was discovered over the entire area of the tumor, and auscultation failed to detect the fetal heart beat or the placental souffle. Her attending physician was asked to withdraw, and the statement was made that the woman was probably not pregnant, which remarks were greeted with a pitying and incredulous smile. It was then suggested that a vaginal examination should be made, and that no harm could result under the circumstances from the introduction of a uterine sound. This was agreed to, and, returning to the patient's room, a speculum was introduced, through which the writer passed a sound. Some difficulty was experienced in reaching the external os, and a considerable degree of force was used in passing the internal os, when, to the amazement of all concerned, there was a rush of pent-up gas in the operator's face, which was most sensibly felt, and which lasted probably not less than half a minute. This air or gas was entirely devoid of odor. For a few moments neither the physician nor the patient could be made to believe that the trouble was over, but a view of the abdomen dispelled all further illusions. A more careful vaginal examination showed that the cervix had been the seat at one time of extensive inflammatory action, and the cicatricial tissue had probably occluded the orifice of the uterus. There was absolutely no information that could be obtained from the patient that would lead to any explanation of her curious condition. She had always been a healthy woman, and remembered no miscarriages within quite a long time; in fact she was not sure she had ever had one, and had never been ill with the exception of 'womb trouble,' for which she had been treated by my professional brother."

A large collection of other cases, considering the rarity of the affection, is made from medical literature. In general they may be said to represent two forms of the disease, one, like that of the author, which by an accumulation of gas due to an occlusion of the os, usually from old inflammation, comes to simulate pregnancy, and the other, which discharges the gas from time to time, causing no great dilatation of the uterus, but giving excessive annoyance from the crepitus produced, so that its victim is obliged to forego society altogether.

Regarding the cause of this singular malady, little seems to be definitely established. The author inclines to the belief that the gas is a morbid secretion from the uterine mucous membrane, citing the authority of Dalton, that every organized tissue has the power of absorbing oxygen and exhaling carbonic oxide. In certain cases where the gas has been fetid there is reason to believe that it has been due to the decomposition of retained decidua membranes or other effete products of the uterus. Dr. Charles D. Meigs is cited as believing that this is the only way in which any gas can be generated within the uterus, he scouting the idea of there being any secretion of gas by the lining membrane of that organ. This latter authority adds that air may be drawn into the womb by suction from without, as that viscus relaxes after expelling clots or other debris in the early part of the puerperium. This is the only condition under which Dr. Meigs ad-

mits that any other than a fetid gas can occur in the uterus. Dr. Yarrow admits this piston-action of the uterus after labor, but considers that phenomenon wholly inadequate to explain such cases as that of his. His theory of secretion is the one held apparently by a majority of those who express any opinion on the matter.

PRESYSTOLIC MURMURS, ORGANIC AND INORGANIC.

In the *Practitioner* for June are quoted some observations on the organic and inorganic causes of presystolic mitral murmurs from Dr. A. E. Sansom, in his Lettsomian lecture on mitral stenosis. He describes the two principal forms of contraction, — the commoner button-hole variety, in which the adherent valve segments viewed from above form a flat, hymen-like surface, presenting a narrow transverse chink at the centre, and the much rarer "funnel mitral," a hollow cone with a round orifice at the summit projecting into the ventricle. He holds, therein differing from Balfour, that the murmur is not necessarily associated with the final auricular contraction, but, though intensified by this, may be and often is produced by the mere force of friction of the inflowing blood during *diastole* after being pent up in the resilient left auricle and pulmonary veins. In support of this view he relates a case in which a presystolic murmur from stenosis co-existed with a left auricle lined with clot, so as to render contraction of its wall impossible. He also urges as another proof the fact that the murmur of the mitral stenosis is often more strictly diastolic than presystolic. In such cases it is very difficult to diagnose from diastolic aortic murmur, especially when the latter is best heard at the apex of the heart. Another possible source of fallacy is friction from pericarditis over the auricles.

Contrary to the general teaching that this murmur is always conjoined with disease of the mitral valve, Dr. Austin Flint cites cases to show that a presystolic mitral murmur may occur with a healthy mitral valve. In these cases the left ventricle was dilated and hypertrophied; the mitral valve, post mortem, normal and competent, and the coronary arteries narrowed. A systolic murmur existed along with the presystolic. He explains the latter thus: The curtains of the mitral valve are pushed up and apposed, though not firmly, by the blood flowing in from the left auricle during ventricular diastole. Then follows auricular contraction, causing a jet of blood to fall on the central point of the apposed curtains, producing vibration of these and consequent presystolic murmur. He compares this to the vibration of the lips when a current of air is sent through them. He considers gradual disappearance of such a murmur a bad omen, probably indicative of loss of power in the auricular wall.

URINARY CASTS OUTSIDE OF BRIGHT'S DISEASE.

In *Lyon Medical* (July 22, 1883) we notice a report of some cases in which casts were found in the urine of individuals suffering from acute non-renal diseases, in whom an autopsy supplemented by microscopical examination confirmed the entire absence of any lesion of the kidneys. The first was a man of fifty-one years, deaf, who had pneumonia. The urine

was bloody, with a considerable quantity of albumen. The autopsy showed, besides lobar pneumonia, chronic endocarditis without valvular insufficiency, atheroma of the aorta, and a slightly cirrhotic liver. The kidneys were absolutely healthy macroscopically and histologically. During life the urine, examined at first without coloration, showed besides red blood globules in considerable quantity hyaline casts, very transparent, quite short, some covered with little granular deposits of epithelial detritus. The examination of the sediment stained with picro-carmin and osmic acid showed the same casts in great numbers, some absolutely hyaline, others more or less covered with granular matter.

A second patient was a man who also died of double pneumonia. The kidneys, normal in gross appearance, presented no noticeable lesion of the epithelium microscopically. During life his urine, normal in color, had shown a large disk of albumen. Microscopically, without staining, there were found in the urine numerous waxy and granular casts. The sediment, after staining,

showed also many casts, some almost perfectly transparent, others formed of granular matter more or less dense, yellowish, and sometimes slightly rose-colored.

Other cases are cited where no autopsy was had on account of the recovery of the patients, but where the author believes from the subsequent history that no renal lesion existed. One was of aortic insufficiency and cardiac irregularity with transitory albuminuria. A few waxy casts were found, but no granular ones. Another man who had acute bronchitis with tricuspid regurgitation and œdema had many casts in the urine, mostly transparent and homogeneous, but some with fissured edges, and others granular. In both the cases the albuminuria rapidly disappeared, and the patients were discharged cured.

In view of the interest attaching to such cases, it is to be hoped that further investigations will be made in a sufficient number of instances to cast further light on the question of tube casts in individuals not having Bright's disease.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 11, 1883.

Cities.	Population by Census of 1880.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 3076 (no report from New Orleans): under five years of age, 1559: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 1074, diarrhoeal diseases 743, consumption 370, diphtheria and croup 123, lung diseases 111, typhoid fever 71, scarlet fever 42, whooping-cough 28,

malarial fevers 19, cerebro-spinal meningitis 18, measles 16, erysipelas five, puerperal fever four, small-pox four, typhus fever one. From scarlet fever, Boston eight, Philadelphia seven, Chicago six, Brooklyn five, New York four, Baltimore three, Pittsburg, Buffalo, and Milwaukee two each, St. Louis, Cincinnati and Chelsea one each. From whooping-cough, New York

seven, Brooklyn, Chicago, and District of Columbia four each, Philadelphia, Cincinnati, and Lynn two each, Baltimore, Pittsburgh, and Providence one each. From *malarial fevers*, New York 12, Baltimore three, St. Louis, Cincinnati, Buffalo, and Springfield one each. From *cerebro-spinal meningitis*, Boston four, New York, Baltimore, Buffalo, New Haven, and Lowell two each, Cincinnati, Worcester, Newburyport, and Spencer one each. From *measles*, New York 10, Baltimore two, St. Louis, Pittsburgh, Worcester, and Lawrence one each. From *erysipelas*, Philadelphia two, New York, Chicago, and St. Louis one each. From *puerperal fever*, Brooklyn, St. Louis, Buffalo, and Providence one each. From *small-pox*, Philadelphia four. From *typhus fever*, New York one.

Seven cases of small-pox were reported in St. Louis; scarlet fever 37, typhoid fever 31, diphtheria 22, and measles five in Boston; scarlet fever 10, and diphtheria six in Milwaukee.

In 34 cities and towns of Massachusetts, with an estimated population of 1,061,441 (estimated population of the State 1,922,530), the total death-rate for the week was 25.72 against 26.53 and 28.43 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending July 28th, the death-rate was 20.1. Deaths reported 3325: acute diseases

of the respiratory organs (London) 161, diarrhoea 413, measles 114, scarlet fever 90, whooping-cough 58, fever 40, diphtheria 20, small-pox (London six, Birmingham, Liverpool, and Newcastle two each) 12. The death-rates ranged from 10.6 in Birkenhead to 25.5 in Manchester; Blackburn 13.9; Bristol 15.4; Bradford 15.8; Wolverhampton 16.2; Birmingham 18.6; Sheffield 19.4; London 21.2; Leeds 21.3; Liverpool 25. In Edinburgh 17; Glasgow 21.7; Dublin 21.8.

For the week ending July 21st, in 168 German cities and towns, with an estimated population of 8,674,730, the death-rate was 32.8. Deaths reported 5477; under five years of age, 3523; diarrhoeal diseases 699, consumption 529, lung diseases 310, diphtheria and croup 138, measles and röteln 106, scarlet fever 70, typhoid fever 62, whooping-cough 50, puerperal fever 17, small-pox (Heilbronn four, Frankfurt a. M., one) five. The death-rates ranged from 14.7 in Lubeck to 52.6 in Berlin; Königsberg 36; Breslau 42; Munich 36; Dresden 31.5; Leipzig 36; Hamburg 23.4; Cologne 36; Frankfurt a. M. 26.9; Strasburg 31.6.

The meteorological record for the week ending August 11th in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

Date.	Barom-eter.	Thermom-eter.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM AUGUST 10, 1883, TO AUGUST 17, 1883.

BAXTER, JEDEDIAH H., chief medical purveyor U. S. Army. To proceed to San Francisco, California, via St. Louis, Missouri, on public business connected with the Medical Department, and on completion thereof will return to his station. Paragraph 1, S. O. 185, A. G. O., August 11, 1883.

MCPARLIN, THOMAS A., lieutenant-colonel and assistant medical purveyor. Relieved from duty in charge of the purveying depot in San Francisco, California, to take effect September 1, 1883, and will then proceed to New York city and relieve Assistant Medical Purveyor Ebenezer Swift of the charge of the purveying depot in that city. Assistant Medical Purveyor McParlin will transfer all funds and public property in his possession to Medical Storekeeper Henry Johnson, who, until further orders, will perform the duties of acting assistant medical purveyor at the purveying depot in San Francisco. Paragraph 5, S. O. 183, A. G. O., August 9, 1883.

BARNETT, RICHARDS, captain and assistant surgeon. Granted leave of absence for one month on surgeon's certificate of disability. Paragraph 2, S. O. 149, Department of the East, August 10, 1883.

BURTON, HENRY G., captain and assistant surgeon. Relieved from duty at Fort A. Lincoln, D. T., and assigned to duty at Fort Assiniboine, M. T. Paragraph 1, S. O. 141, Department of Dakota, August 11, 1883.

BANISTER, JOHN M., first lieutenant and assistant surgeon. Relieved from duty in the Department of the Missouri and assigned to duty in the Department of the East. Paragraph 5, S. O. 183, A. G. O., August 9, 1883.

BENHAM, R. B., first lieutenant and assistant surgeon. Relieved from duty at Fort Assiniboine, M. T., and assigned to duty at Fort A. Lincoln, D. T. Paragraph 2, S. O. 141, Department of Dakota, August 11, 1883.

CARTER, WILLIAM F., first lieutenant and assistant surgeon. Relieved from duty in the Department of Texas and assigned to duty in the Department of the East. Paragraph 5, S. O. 183, A. G. O., August 9, 1883.

KANE, JOHN J., first lieutenant and assistant surgeon. Relieved from duty in the Department of the Missouri and assigned to duty in the Department of the East. Paragraph 5, S. O. 183, A. G. O., August 9, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING AUGUST 18, 1883.

BRIGHT, GEORGE A., surgeon. Temporary duty at Naval Rendezvous, Philadelphia, Pa.

NEILSON, JOHN L., surgeon. Temporary duty on board Receiving Ship Franklin, Norfolk, Va.

MARTIN, WILLIAM, assistant surgeon. Navy Yard, Pensacola, Fla.

BOOKS AND PAMPHLETS RECEIVED.—Twenty-Eighth Annual Report upon the Births, Marriages, and Deaths in the City of Providence for the Year 1882. By Edwin M. Snow, M. D., Superintendent of Health and City Registrar. Providence, 1883.

CONGENITAL DISLOCATION OF THE HIP.¹

BY ABNER POST, M. D.

CONGENITAL dislocation of the hip is by no means a common affection, though probably not so rare as has been supposed. I have some scanty notes of four cases which I have seen within the past two months, and have previously seen others, of which my remembrance retains no striking difference from the later cases. In each case the diagnosis has been confirmed by competent observers, and I propose to give a few observations upon the subject, based upon my own cases.

Of these four cases, three were seen at the out-patient department of the Children's Hospital, the fourth was seen with Dr. Bradford through the kindness of Dr. Leonard.

My notes were taken in haste and are very imperfect, but are given for what they are worth.

The cases mostly dwelt upon in the books are those of dislocation of both hips. All my cases were of one hip only. The double dislocation has naturally attracted more attention than the single lesion, though, to my mind, the single dislocation is the more important, as offering less striking points for diagnosis, and being therefore more easily overlooked. The importance of the subject lies in great measure in the diagnosis from hip disease, for which it is liable to be mistaken.

Of these four cases three were born with head presentation. In one of the cases some accident was said to have happened to the child at birth, and a leg was encased in plaster on the following day, but it is solemnly asserted that the plaster was applied to the leg now found to be normal. Another case was a forceps delivery. Nothing abnormal beyond this was found in any of the cases during early babyhood. No history was obtained of any particular deformity or sensitiveness during that period. In the case in which attention had been drawn particularly to the legs anything unusual would probably have been noticed; the other cases belonged to families in which the powers of observation were less educated, and in one case, on account of the imperfect knowledge of English on the part of the parents, no definite history was obtained. All the cases were thought to have been a little late in walking, and a limp was noticed from the first. All the children when seen were healthy, though one was certainly not robust. In each child the leg was decidedly shortened; in one girl of eight years the shortening was over two inches, and they all walked with the limp due to such a difference in the length of the limbs; in no case was there decided eversion or inversion noticeable in ordinary walking.

On stripping the children and placing them on the table no special deformity or wasting was noticeable beyond the shortening and the prominence of great trochanter and the lordosis; flexing hips and knees showed the tibiae to be of equal length and the shortening to be confined to the femur; the fingers on the great trochanters showed that on the affected side to be decidedly raised; a line drawn from the anterior superior spine to the tuber ischii (Nélaton's line) passed below the trochanter. Motion at the hip was in three of the

cases free, the fourth case I shall mention separately. There was none of the limitation of motion found in morbus coxæ; it was motion at the hip and not movement in the lower vertebrae, and was freer than usual, save in abduction; abducting the leg a decided resistance was met; motion took place, however, at a point nearer the sacrum apparently than on the sound side. Absorption of the head of the femur seemed to have taken place in some of the cases, at any rate it was not always possible to distinguish it.

The children were brought for consultation because of the fears excited by the limp rather than for any suffering on the part of the child, though one of them suffered from wandering pains in the back and legs, and was easily tired. Generally some suggestion of hip disease had served to augment the parent's anxiety.

The fourth case was two years old. Her birth was instrumental head presentation. She began to walk at eighteen months, and was lame from the first. During the past summer (1882) she was said to have had abscesses on her back, but no scars remained. During the last summer she also had a fall of some severity, but it had caused no change in her walking. The mother complained that the child slipped and fell on the slightest provocation, and even on the smooth floor. There was no pain or other symptoms. She walked with a well-marked limp, and the trochanter could be seen to move up and down with each step.

Stripping the child showed atrophy of the leg and prominence of the great trochanter, which was above Nélaton's line. When she was suspended by the shoulders there was marked eversion of the foot. Examination showed marked freedom of motion at the hip-joint, and at times a smooth cartilaginous slip like that of a bone in and out of its socket. It was not easy to determine whether this was the head of the femur slipping in and out of the acetabulum or slipping over an imperfect new socket, but it brought within reach a process which felt like an imperfect head of the femur. The position of the trochanter seemed to negative the supposition that this imperfect head slipped in and out of the acetabulum. All examinations were made unusually difficult by the determined resistance of the child; and as she was expected to enter the hospital, where examination could be made at leisure, prolonged attempts to gain more accurate data were postponed.

This case is especially interesting as showing that cases are not uniform. It was the only case in which the slip of cartilage could be felt.

This child presented opportunities for treatment not presented by the others. If it returns for treatment an attempt will be made to return the head to its proper position, or, that failing, to adjust a retentive apparatus which shall prevent it slipping about, which is the cause of the frequent falls.

In the other cases the only treatment attempted was the use of a high shoe, which in the case mentioned as complaining of pain in the back, etc., was instrumental in relieving that pain, and in making locomotion very much less fatiguing.

It is certain that many cases have been greatly improved by treatment. It is equally sure that a time comes when all attempt to reduce the deformity is unavailing.

This trouble is said to be often hereditary. Evidence on this point was not sought, but the mothers were all seen and none of them were lame. A very large majority of recorded cases are female. On the

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 7, 1883.

point of sex my memory allows me to add two cases to the four mentioned. Of these six cases five were girls.

The secondary effects of the lesion demand notice as they may be very serious. Lateral curvature of the spine may follow this as it does other lesions which cause inequality in the length of the limbs. An unequal development of the pelvis follows the single rather than the double dislocation.

These cases are always dislocations upon the dorsum. It is in that position that the head, or whatever remains of it, is felt. Other varieties of congenital dislocations of the hip have been reported, but only in children otherwise deformed, and ordinarily in monsters. Congenital dislocations of other joints sometimes occur, but with these we are not concerned.

The origin of the trouble is uncertain and its consideration is very interesting. Many hypotheses have been advanced. The first and most obvious is that they result from violence during parturition. It would seem that such an occurrence might readily take place during birth with a breech presentation when the use of the blunt hook or even of the fingers might have a tendency to draw the head of the femur out of the acetabulum. The position of the head of the femur when the thighs are strongly flexed would be the most favorable for its escape from its socket, but the writer in the *Dictionnaire de Médecine* has found it impossible after many trials to cause the dislocation in this manner, and it is not easy to see how such an accident could be caused during birth by the head presentation. Violence to the mother previous to parturition, a blow being transmitted through the uterine walls to the knees of the child, or the contractions of the uterine walls acting in the same manner, has been adduced as a cause. The position of the fetus in utero with the thighs flexed upon the abdomen brings the heads of the femurs in contact with the posterior and inferior portion of the cotyloid cavity. At this stage of development it will be remembered that the cotyloid cavity is exceedingly shallow, and the seat of union of the thin bones of the pelvis, and offers much less resistance to the exit of the bone from its cavity than later in life.

Dupuytren advanced the idea of an original vice of conformation depending upon the original constitution of the germ.

Borschet refers this luxation to an arrest of development in the cotyloid cavity.

Intra-uterine joint disease is another theory which was advocated by Paré and by others since his day. It is highly improbable, however, that any process similar to morbus coxarius, as seen in children after birth, could take place without, in some cases, leaving traces of the inflammatory process and a stiff joint behind it.

Carnochan, who is the author of a very complete monograph on the subject of Congenital Dislocation of the Hip, believes in a perverted condition of the excitomotor apparatus of the medulla spinalis. In his somewhat lengthy argument upon the subject he says: "I should say, then, that the congenital displacements occurring at the ilio-femoral articulation result from active morbid muscular retraction; that morbid muscular retraction itself is to be traced to a morbid condition of the central ganglionic mass of the cord, and that this pathological condition is either located in the ganglionic mass or conveyed thither by the incident-excitor nervous influence of the excitomotor apparatus of the medulla spinalis."

It is not necessary to catalogue all the supposed causes nor to suppose that these cases are all the result of the same cause. It is certainly possible that different causes may cooperate to produce the result.

To one acquainted only with the literature of the subject the diagnosis of such cases as have fallen under my observation present certain difficulties. The books dwell particularly upon the double dislocation and upon the presence of the head of the femur upon the dorsum of the ilium. It seems worth while, even at the risk of repetition, to give in detail the diagnostic points of the single dislocation, as my experience leads me to think that its recognition is a problem which may be presented to any one, and which presents no especial difficulties when once the subject is brought before the mind. I dwell upon the diagnosis because the little incidents told by my patients in regard to their search for a diagnosis lead me to believe that it is not ordinarily recognized. One of the cases seen had been told by a distinguished surgeon, now dead, of another part of New England, that the child would outgrow the trouble, and walk all right after a time, a prediction which, of course, has not been verified, and, of course, has not added to the faith of the family in the profession. Children have been leeches, blistered, and cupped, confined to bed, and treated with all sorts of machines through misapprehension as to the nature of the difficulty.

A history of a limp from the time of the first step in a child which began to walk late, the limp increasing as the child grows, and unaccompanied by febrile action or any special pain, should turn the attention to the possibility of a congenital dislocation. If such is the lesion, when the child walks the trochanter may be seen in some of the cases to rise higher towards the anterior superior spine of the ilium as the weight is thrown upon the shorter leg. When the child is stripped and laid upon the table the difference in contour of the legs is not very striking. Squaring the pelvis the limbs lie side by side; there is arching of the back, and marked shortening of one leg. One malleolus rises markedly above the other. The same is true of the inner condyles of the femur. Extension of the shorter leg reduces the difference somewhat, probably not entirely; flexing the knees and thighs as in the sitting posture makes it plain that the difference in length is confined to the femora. The trochanter is higher on the shorter limb, and Nélaton's line shows the trochanter above it. There may be a vacuity in the groin, and the line of the vulva, if the child is a female, may be deflected. Behind the gluteal fold is raised somewhat, but not obliterated, and the line between the nates is deflected.

Examination shows a want of sensitiveness about the hip, and unusual flexibility in the joint save in abduction. If the examiner is looking for decreased motion in the joint, his attention may be concentrated on the sound limb by its relative rigidity.

Abduction is limited in some of the cases. Sometimes, but not invariably, the head of the femur may be felt upon the dorsum or be brought within reach by manipulation.

"When the patient was sick the patient most grateful would be,
When the patient got well the patient disputed the fee."

APOPLEXY OF THE CEREBELLUM.

A CASE IN PRIVATE PRACTICE.

BY E. P. HURD, M. D.

SUBJECT, T. R., aged seventy-five, a retired merchant. *Hereditary Antecedents.* Father, possibly also mother, died of apoplexy at an advanced age.

Previous History. Mr. R. had enjoyed good health till the night of the apoplectic seizure. Had led a quiet and easy life. To oppose a tendency to corpulence he had adopted a milk diet. Never indulging in ardent spirits to excess, he nevertheless took daily, generally before meals and before going to bed, a little whiskey. July 30, 1883, he ate a hearty supper of bread and milk, and drank a little milk and whiskey before retiring. At eleven o'clock P. M. he was found comatose, breathing stertorously, with left-sided hemiplegia, and right facial paralysis (crossed paralysis). Dr. F. A. Hale, of this city, was summoned, but could do nothing. There was the most profound coma, with relaxation of all the members, contraction of the pupils, paralysis of deglutition, weak, irregular pulse, and marked Cheyne-Stokes respiration. The heart's action became more and more faint, and in five hours from the inception of the attack death ensued.

Autopsy twenty-four hours after death. There were present Drs. Hale, Bolton, and myself. Only the encephalon (by request of the family) was examined. General vascular engorgement of the meninges and substance of the cerebrum. Blood-vessels of the circle of Willis seemed healthy. Venous sinuses all full. Otherwise there was nothing worthy of note till the tentorium was removed and the cerebellum examined. The right hemisphere of the cerebellum contained a large clot, which had excavated for itself a place, and had effected complete disorganization of the nervous substance. The weight of the clot was estimated at two ounces. The subjacent portions of the medulla and pons presented an intensely congested appearance. Superiorly the clot extended in the form of a thin, firm layer over the whole of the right hemisphere and superior vermiform process to the other side; inferiorly and to the right it followed the middle peduncles to the pons, where it stopped, involving the origin of no nerves except the seventh pair, which was found imbedded in the clot and thoroughly disorganized. On examining the arteries the occipitals and the basilar were found to be intact, but the right superior cerebellar and all its branches were filled with recent coagula which extended almost from the junction of this artery with the basilar into the right hemisphere of the cerebellum. This gave probability to the supposition that the hæmorrhage had proceeded from a small branch of the superior cerebellar in the cerebellum; all the arteries of this region, moreover, were markedly calcareous.

The involvement of the portio-dura in the clot of the right side explained the occurrence of the right facial paralysis. The situation of the large clot in the cerebellum contiguous to and pressing upon the *right motor strands* of the pons and medulla explained the left-sided hemiplegia. The propinquity of the medulla oblongata with its important cardiac and respiratory centres and the fatal embarrassment to the functioning of this part of the cerebro-spinal axis occasioned by the lesion were sufficiently obvious facts.

Hæmorrhages into the cerebellum are comparatively rare forms of apoplexy. On looking over files of the

Boston Medical and Surgical Journal of the past twenty-five years I have not been able to find recorded a case. Bastian, in his useful work on Paralysis from Brain Disease, hardly alludes to it, but in an interesting lecture published in the *Lancet* for 1878 he treats of the subject quite fully. When the hæmorrhage is extensive there will always be hemiplegia on the opposite side, not in consequence of lesion of the cerebellar tissue, but from pressure on the corresponding side of the pons and medulla. If the hæmorrhage be trifling there may be no paralysis or even coma; cephalalgia and vomiting are then prominent symptoms.

Luy's¹ reports several very interesting cases which were characterized by sudden loss of consciousness, with hemiplegia on the opposite side to the lesion, death speedily ensuing.

REPORT ON MATERIA MEDICA AND PHARMACY.

BY WILLIAM P. BOLLES, M. D.

ABSTRACTS.

DR. SQUIBB is publishing in his *Ephemeris* a long and careful criticism upon the new Pharmacopœia, four installments of which have already appeared, and are full of sound observation, and rich in practical pharmaceutical knowledge. As he takes up the subjects alphabetically, abstracts come in for an early notice, and are not very cordially received, as will be seen by the following quotation: after copying the statement from the preface of the Pharmacopœia that "to supply a demand which has arisen for dry, powdered extracts a new class of preparations has been introduced under the title of Abstracts," the doctor says, "The demand for a class of dry, powdered extracts has, in the writer's experience, not been great, and what demand there was came from pharmacists rather than from physicians. Several powdered extracts have been long in common use, and a few others have been more recently advertised into use, the supply being used to create a demand. There is, however, an undoubted advantage and convenience, or, perhaps, a necessity, for having a few powdered extracts. And for having these to bear an accurate, known relation to the drug, and for having official formulas for such, but whether these abstracts fulfill the conditions in the best way may be doubted." The process by which they are made appears to him troublesome, expensive, and hurtful, and the degree of concentration would have been better if, instead of attempting uniformity by reducing them until they weigh one half as much as the crude article, those which would admit of it had been made three or four times as strong, with a correspondingly less dose. He then examines each one of them with much pharmaceutical detail, and offers for them a substituted process, which must have occurred to most persons who have examined the directions of the Pharmacopœia, namely, evaporating the fluid extracts, and properly diluting, excepting in the case of jalap, where the alcoholic extract is not likely to be injured by the heat, and in those of ignatia, which he ignores, and of podophyllum, which he condemns entirely. The process which he proposes consists (in brief) in taking a small quantity, say thirty cubic centimetres, and spreading it out upon a large surface,

¹ Recherches sur le Syst. Nerv. Cerebro-Spinal, page 581.

that is, a dinner plate, so that it shall evaporate spontaneously in twenty-four or thirty-six hours, then scraping it off, warming a little if necessary, adding the sugar of milk in the proper quantity, and rubbing fine. The abstract of conium, made by the official process, he is almost certain would be inert, and that of valerian "made with great care and with all the skill of which he was capable" was unsatisfactory when compared with the fluid extract from which it was made."

Apropos of the demand for these preparations, in an examination of ten thousand recipes from the files of one of the leading apothecaries of this city, covering regularly distributed portions of a period of two years, ending last July, not a single abstract was called for.

CONVALLARIA MAJALIS.

Considerable attention has been given to this little plant within the past twelve or more months, but the evidence of its great or special usefulness is not yet altogether convincing. It is not by any means new to medicine, and its active principles were separated as long ago as 1858 by Valz. The leaves and flowers as well as the roots have all been experimented with. The observations which gave it its present start, however, were those of Professor Sée, which, although not by any means conclusive, were nevertheless sufficiently interesting to direct considerable attention to it, and cause a repetition of his trials with it, as well as a reëxamination of its chemical characters. The two peculiar principles discovered by Valz, and named convallarin and convallamarin, are both light-colored amorphous powders, both glucosides, and both separable without special difficulty in a state of approximate purity. Of these the first named is inert, or at least does not represent the heart-toxic qualities of the other, and this latter, therefore, as far as we know, must be taken to represent what is valuable in the plant. But neither the chemical examination nor especially the therapeutic value of the drug can be considered as fairly proved, and the principal object of this note is to call attention to it for further trial. No doubt some of the discrepancy of the results of the experiments of different observers is due to want of care or judgment in regard to the time of the year when the roots, etc., were collected, as well as the employment of different parts of the plant. The fluid extract of the root may be given in doses of from five to twenty drops.¹

ICHTHYOL.

An artificial compound obtained by treating one of the products of the distillation of a certain bituminous rock of Seefeld, in the Tyrol, with sulphuric acid. The bitumen is found associated with numerous remains of extinct fishes and other animals, and, according to Professor v. Fritsch, is probably a product of their decomposition. This is rendered plausible by the fact that it contains the basic substances found in bone tar oils. Ichthyol is made by distilling the rock, saving the dark, tarry oil, purifying it, and treating it with concentrated sulphuric acid. A salt is formed which, when freed from the excess of acids, contains ten per cent. of sulphur, and is the product in question. It is a tarry-looking liquid, having a peculiar herb-like odor, a faintly alkaline reaction. It has about the consistency of vaseline, with which it is miscible in all

proportions. It is partially so in ether and alcohol, and wholly so in a mixture of the two. It is recommended as a valuable ointment in cases of chronic eczema, diluted one half or more with vaseline or lard.²

CITRATE OF IRON AND QUININE.

Dr. Squibb sees a step backward in the modern use and some of the modern preparations of this salt. It was originally introduced, according to the doctor's account, to furnish an almost tasteless preparation of quinine; still one that had a large proportion of that alkaloid in it, and one, too, in which it was finally completely soluble. These requirements the citrate of iron and quinine almost completely satisfied. It could be taken as a powder or pill, uncoated, or be mixed with syrup, and taken without repugnance, if administered immediately; while, on the other hand, it is soluble in its own weight of water if time enough is allowed. Instead, however, of taking advantage of these most desirable qualities, it is an undisputable fact that this preparation is now generally given in a very bitter solution, and to render its solubility more rapid citrate of ammonia is often added with the effect of considerably weakening the alkaloidal strength, while it renders the compound readily soluble. Citrate of iron and quinine, then, should be given dry or merely suspended in fluid, and the most insoluble is the best in quality.

PERSIAN OPIUM.

Two consignments of Persian opium were recently received in New York. It came packed in cases of 130 pounds each, in lumps weighing about thirteen ounces each. These lumps were plano-convex, as if they had been round balls flattened when soft by resting upon a flat surface to bake or to dry, smooth, polished, of a dark-brown color, with a brittle "shell" and softer interior. Their texture was homogeneous excepting as just mentioned. Assays were made of the two lots, and showed them to be of excellent quality, the first yielding between ten and eleven, and the second thirteen per cent. of morphia, calculated upon the weight undried.³

— According to the *Medical Times and Gazette* the sign "Ry," which Dr. Holmes has explained as a relic of the astrological symbol for Jupiter, and which as such is not specially flattering to the physician's claim as a devotee of pure science, has received another gloss which can hardly be said to be preferable on this ground to that commonly given. It seems that at the close of the sixteenth century Dr. Dee was, according to his own account, and apparently his own conviction, on terms of intimacy with most of the angels. His brother physician, Dr. Napier, got almost all his medical prescriptions from the angel Raphael, and Elias Ashmole had a manuscript volume of the receipts, filling about a quire and a half of paper. Now it has been thought that the prefixed characters which Ashmole interprets to mean *Responsum Raphaelis*, remarkably resemble that cabalistic-looking "Ry" which is to this day prefixed to medical prescriptions, but is commonly interpreted *recipe*.

Hospital Practice and Clinical Memoranda.

CLINICAL REPORT ON CASES OF LACERATED CERVIX, FROM PRIVATE PRACTICE.¹

BY JOSEPH H. WARREN, A. M., M. D., BOSTON, MASS.

FROM observations of over twenty-five years I have learned that lacerations of the cervix uteri occur much more frequently and extensively on the right side than on the left, but that when both sides are lacerated the left is usually torn more than the right. The most natural question is, Why should this laceration occur so much more frequently and extensively on the right than on the left side, and to this question I can give no other answer than that, in many cases at least, the laceration is due to bad and meddlesome midwifery. I do not mean that the obstetrician should never interfere with the progress of a labor when by such interference he may render the necessary assistance that is all-important to the successful termination of a labor that is already unduly protracted; nor do I mean that the accoucheur should be blamed if in rendering such necessary assistance he consciously or unconsciously lacerates either the cervix or the perineum. A laceration in some cases is probably inevitable, and the fault is no more with the physician than with nature. But there are certain ways of conducting a labor that must be censured by every conscientious practitioner, and it is to these gross mismanagements that I apply the term bad and meddlesome midwifery.

The cause of lacerations in general is a weakened state of the woman's constitution, a child abnormally large for the woman's pelvis, which is often narrow and contracted, the correction of some malposition or malpresentation, or the use of instruments, or in some cases a natural but a too rapid labor. I recall a case which is interesting and instructive in many ways.

Mrs. O. B., of Dorchester, became pregnant with her first child when she was forty-seven years of age. I was called to her June 1, 1857, and found that she had considered herself pregnant for about six weeks. Her history was that on the very next day after connection with her husband she began to complain of nausea and vomiting, so that she could retain nothing either solid or fluid upon her stomach. I attended her almost daily during the whole of her pregnancy, and can rely upon her statement that she was able to retain nothing upon her stomach during all this time, unless, possibly, it might be a little beef or lamb scraped fine and mixed with sugar and champagne. Although she was nourished by injections of beef tea and milk she became much emaciated by the time of her confinement. Her labor was protracted for three days, but at last I succeeded in dilating the os sufficiently to introduce the blades of the forceps and deliver a large and healthy female child. In doing this I lacerated the cervix upon both sides, slightly on the right but pretty extensively on the left, but not extensively enough to require an operation for lacerated cervix. I consider the reason why in these double lacerations the left side is torn more than the right to be that with the woman lying upon her back or left side we are inclined to pull up in making traction upon the forceps, and thereby cause a corresponding depression of the ends of the

blades, which cuts and tears the left side more than it does the right.

Another feature of this case which I will mention is that the patient's nausea and vomiting could be controlled for the space of three or four days by the application of tincture benzoin comp. to the cervix. This can readily be applied by adding to it elastic collodion. The late Dr. Miller, of Dorchester, in his practice used the tincture of iodine for the same purpose, and both his article and my own upon this subject can be found in the Boston Medical and Surgical Journal.

The next case of a laceration of the cervix that I remember was in a labor where the cord had prolapsed. While I was vainly attempting to hang the cord upon some prominent point of the child that I might hope to find, and when I had just succeeded in pushing back the loop within the os, a sharp pain came on, caught my finger in the os, and ruptured the cervix upon the right side. Another laceration took place upon the right side while I was attempting to change an arm and shoulder presentation into a footling, and still another while I was assisting a physician to deliver a dead child with the blunt hook. The hook was introduced on the left side of the cervix, and had caught the left side of the lower maxilla, but the traction was toward the right side of the os, and hence the laceration was upon that same side.

There are, however, two classes of lacerations that are needless, and are due to improper interference, meddlesome if not directly criminal. Some practitioners will try to assist the progress of the labor by helping nature to dilate the os, even when the labor is progressing as rapidly as it ought. By fingering the os they make both it and the vagina hot, dry, and irritable, and if the patient continues to bear down constantly, as they wish her to do, the time will speedily come when the os will tear. If this was caused by ignorance we might hope to root out the evil, but I am afraid it arises in many cases from impatience and willful carelessness. But the most criminal lacerations are those produced by those vipers in the community, the miserable and soulless abortionists. To produce a miscarriage, and to free a woman of the inconvenience of carrying her child, these wretches cut her, and almost always upon the right side of the cervix. Indeed, I believe this injury to be one of the prime causes of death after an attempted abortion, by causing an acute septicæmia, and I think it would be an interesting study for the medical examiners to ascertain what proportion of those dying from abortion have a lacerated cervix. I have sometimes thought it a fit punishment designed by Providence for those who yield to this great sin, and I feel confident that many more lacerations than we now suspect have been caused in this way, even among our American women, for within a short time I have operated on no less than three such lacerated cervixes due to this cause alone.

It often happens that a laceration exists when we little think it, and to show how easily one may fall into this mistake I will relate a case. I saw a lady three times, but could find nothing more abnormal in her as seen through a bivalve speculum than possibly a slight fissure which I should not think of repairing. She went to another medical gentleman, who was so positive of his position that he was willing to take oath that she had no laceration. Finally she went to a distinguished practitioner, who said she had a terrible laceration, and who operated upon her for it. I am

¹ Read before the Suffolk District Medical Society, February 24, 1883.

willing to confess that my diagnosis may have been a mistake, and for the following reason: the last gentleman used a Sims's speculum probably in his examination, which I think was the proper instrument to use. Recently I have made an operation for a lacerated cervix uteri which to the touch would seem to be only slightly if at all fissured, but which on examination with a Sims's speculum, by which the uterus was drawn down, revealed an extensive laceration winding obliquely around the cervix, the edges of the tear being kept in perfect coaptation. Moreover, this is the second case of the same peculiar kind that I have seen and treated within a year, so that I must ask pardon of my good friend for ever doubting his diagnosis in the case I have mentioned.

These lacerations are by no means always the fault of the physician attending the labor, for similar accidents happen with the best of practitioners abroad, both in private and in hospital practice, and will continue to happen so long as women bear children, unless, indeed, future generations develop more physical perfection than is at present known. But it is to American gynecologists that modern surgery has had to look for the diagnosis and treatment of these cases, and this is only a single instance of the homage Europe has had to pay to us. Indeed, I feel proud to say that I believe that medicine and surgery in all their branches, except possibly pathological anatomy (and this through no lack of ability in our professors), are taught as well, if not better, in Boston and Philadelphia, and I might add the schools at Portland and Bowdoin College and some few others, as in any European schools, those of Vienna and Berlin not excepted.

My usual plan in treating lacerations, particularly those of the cervix, is to take stitches pretty closely together in the lips after they have been thoroughly pared and freshened, and to use the animal ligatures for the upper stitches. The last stitches I usually make with fine silk, either black or white. In addition, in all of my late operations, I pass a very fine animal ligature through the edges of the laceration after drawing the pared lips together by silk sutures. I find this materially assists in obtaining perfect union at the extreme end of the laceration. Then I return the parts into their normal position in the vagina, and leave the silk ligatures in their places for ten or twelve days. The animal ligatures will in time become absorbed, but I consider it a great mistake to remove the silk or silver stitches after they have been in place only six or eight days, as recommended by most authors. The tissues of these parts do not heal so rapidly as in other portions of the body, and I have found by experience that better results are obtained if we allow the stitches to remain for twelve or fourteen days. They cause no trouble by remaining this length of time. After forty-eight hours have passed since the operation I have the vagina well washed out night and morning with a solution of carbolic acid or a solution of thymol in glycerine. In twelve or fifteen days the parts will usually be found to be well healed; but if the first operation should not be successful another should be performed after a few weeks or months, or as soon as the constitution of the patient will allow without producing too much depression or shock, for it will be found that very many of our failures in this operation are due to a want of a proper standard of good health at the time of operating. To illustrate my position more

plainly, I will select out of a large number of cases that I have operated and treated for this quite common affection the few following somewhat interesting ones:—

My first case of lacerated cervix uteri was that of a Mrs. T., of Newton, late in the fall of 1853. Mrs. T. had been bedridden for nearly twenty years from what was supposed to be extensive ulceration of the os and cervix. I operated by applying strong nitric acid and packing the parts well around with fine linen tow. We used tow at that time more frequently than cotton in surgical dressing. She made a fine recovery, the lacerated cervix united perfectly. She regained her health so fully that she was enabled to perform all the duties of a housewife, and she remained in good health for years afterwards. This laceration occurred in a rapid childbirth twenty years before, and took place on the right side, which peculiarity will also be noticed in a majority of the cases that follow. They also illustrate the constitutional severity of these lacerations.¹

Mrs. S., of South Boston, aged thirty-two, was confined with a second child six years previous to the time of the operation. The labor was only of four hours' duration,—very rapid, it will be seen. She felt a certain giving away and shock about fifteen minutes before the birth of her child. She said the man called in was so fearful that he would not get through before my arrival that he pulled and hurt her very much, telling her to bear and force down with all her might, and he would help her by dilating the os, which it would seem was most fearfully and rapidly dilated without any such urging or assistance on his part. I arrived just as the child was born. This man in attendance, not a regular physician, skulked away seemingly with great haste. I found the woman bleeding very profusely, so that I was obliged to plug her, and it required no little effort besides on my part to arrest the hæmorrhage.

Her recovery was necessarily very slow, and upon examining her I found that a terrible laceration of the parts had taken place. I told her that this tissue we would repair as soon as she was in suitable health to undergo the operation. I lost sight of her until October, 1881, when, with the assistance of Dr. W. E. Smith and my son, C. E. Warren, I denuded the lacerated parts and secured them together with carbolized animal ligatures for the upper stitches, the two lower being silver. I found it necessary to take eight stitches. The sutures of silver were removed on the twelfth day, when perfect union of the parts had taken place. For the first few days after the operation she had increased temperature, running up as high as 101° F., and on the fourth day the menses made their appearance. The operation was done under antiseptic precautions. I should remark that both lacerated lips were covered with a soft, velvety growth, and the interstices loaded with pus. This was very friable, and easily broken down under the slightest pressure, so that I was obliged, fearing a malignant tendency of the disease, to remove the tissue for some distance till I arrived to where it seemed healthy and sound before I brought the parts together and closed them with sutures. The patient is now in good health, and the appearance of the uterus is like that of a virgin.

The removal of this softened tissue I speak of was

¹ To fully appreciate this affection see Savag's *Anatomy of the Female Organs*.

extremely necessary, as I once before operated on a case where there was a union which lasted for one or two years, but finally all sloughed out, so that the hiatus was even larger than it was previous to my operation, and the parts were greatly degenerated. Finally cancerous affection took place along the track of our former operation, and nothing more of course could be done, but I felt that had I pared deeper and got more sound tissue there would have been less likelihood of this malignant growth appearing.

Mrs. E., aged twenty-five, had her third pregnancy. She applied to a professional abortionist, and he performed an abortion on her by cutting the right side of the uterus from the external os very deep through the neck and into the body of the organ. She suffered two years from ill health, when she consulted me for uterine trouble. She said she had been to the City Hospital, and the physicians there said it was the most extensive laceration they had ever seen. With the assistance of Dr. C. P. Baucroft I operated after denuding the lacerated parts, and secured them together with six silver wire sutures. On the tenth day I removed them, and found perfect union. No great rise of temperature took place, only a slight feverish condition. Injections of carbolic water were used frequently, and administrations were made of ten grains of quinine sulphate per day. She has enjoyed most perfect health since.

Miss L., of Maine, aged twenty-two, became *en-ciente*, and sought relief at the hands of a notorious abortionist in that State. He operated in a similar manner, cutting very extensively the os and cervix, and into the body of the uterus far beyond the junction of the vagina. This was also on the right side, and a fearful laceration. She suffered, too, from pains of a neuralgic character in both ovaries and uterus, extending down the limbs, with bloating of abdomen and legs. Another serious symptom was irritability of the bladder. Her appetite was poor, and she was sleepless at night. Upon examination all the lacerated parts were found covered with a thick, creamy secretion or mucus, and under the slightest touch the little papillæ underneath bled very freely. After proper constitutional treatment with triple phosphates and bromides, she being apparently in a sufficiently healthy condition to warrant an operation, I operated January 5, 1882, with the assistance of Dr. W. E. Smith and C. E. Warren. After thoroughly denuding, the parts were brought together, and silver sutures, used for the first two lower stitches and for the four upper ones silk. For the lower edge of the os a transverse suture was applied, which greatly strengthens those higher up, and also helps to maintain the position of the denuded parts in a far better manner than when this stitch is not applied. In this case menstruation returned on the eighth day, and the removal of the stitches was deferred until the fifteenth, when the parts were found perfectly united.

The next interesting case was that of Mrs. J., aged twenty-seven, her first confinement having been some six years before. She had a very painful, long, and tedious labor. The attending physician perceived an audible fracture of the os pubis. This was owing to a greatly contracted pelvis. She being threatened with great collapse, the instruments were applied, and in delivering her the cervix was lacerated on both sides, the left very extensively, whilst the right was not torn through the crown of the os. In November,

1880, I operated with the above-named assistants, and after paring and making coaptation of the parts, silver and silk ligatures were used, as in many of my former cases. The patient was slightly feverish the first few days, the temperature rising to 101° F. on one day. On the sixteenth day the sutures were removed, and I found perfect union had taken place. She made a rapid and good recovery, whereas she had been almost bedridden, and was unable to take any exercise for six years previous to the operation. She has ever since been enabled to go where she pleased, and perform all the duties of the head of a family. This is the only case of fracture of the os pubis I ever saw that took place at the time of labor, and we can imagine with what force must have been the contraction of the uterus upon the child that pressed against the os pubes sufficiently to cause that bone to give way.

I might mention other cases. One I recall where the laceration, commencing at the anterior portion of the cervix, passed obliquely around nearly to where it began in front, — really a spiral laceration. This case I for some time treated before discovering that the laceration extended above the crown of the os, but upon a thorough examination of the patient on her side with a Sims's speculum I discovered the extent of this rupture.

Whilst seeing somewhere in the neighborhood of 450 cases of laceration, besides the number that I have already reported, it is astonishing how many of these ruptures require little if any treatment, as the rupture does not extend through the tissue to the crown of the cervix, and will generally heal and the parts become as sound and healthy as any other portion of the tissue comprising the os; but when this laceration extends above the circular muscular band of the os into the cervix of the uterus then it is that it gives rise to this fearful constitutional and nervous trouble and exhaustion, which is often supposed to be due to simple ulceration or some other morbid disease of the neck of this organ, not until within the last few years having been recognized by a very large number of our profession who have undertaken to treat these diseases. There are some lacerations which are external and very apparent; others may require our most thoughtful and rigid investigation, because the laceration, taking place internally, does not show upon the external parts. Many, I might say the large majority, of lacerations that I have seen have been what we may term internal lacerations. They may extend from the upper portion of the uterine neck down through nearly to the os, and are recognized by dilating the organ by the tupelo tent, or, as may be done oftentimes in very large uterine canals, with the dressing forceps, when we will see the fissure on one side extending down through the mucous membranes and extending for some distance into the interior of the uterus. This gives rise to very large and swollen lips and os, with a very great increase of bulk of the uterine neck, so that this portion of the lips and cervix uteri are often much larger than the body of the womb. These cases will go from one practitioner to another and be treated with slight apparent benefit to their irritable uterus and the leucorrhœal discharge which generally accompanies this extensive inflammation, but they soon relapse to be as bad as before, and seek some other practitioner who will relieve them. When such cases come to me I usually dilate and examine them thoroughly, and after I am convinced that there is an internal lac-

eration I apply strong nitric acid or the acid nitrate of mercury, or the actual cautery in some cases (and of late I think much of the galvano-cautery), and it is surprising how soon the patients regain their health, and the enlargement of the lips and the whole organ returns to its normal condition. Many of these cases that I have treated have given me no little reputation in the curing of patients who had sometimes been attended by some of our best authors and practitioners in New York and other cities. Some of these cases are supposed to have been subinvolutions, when in reality they are fissures of the mucous membranes, caused by the birth of a child at full term, or, more likely, a miscarriage at three or four months.

Out of a record of eighty-three operations on lacerated cervixes by denuding the parts and using sutures I have in some ten failed, they requiring a renewal of the operation. Three of these cases I re-operated on with success. The others disappeared, so that I know not what became of them. I have seen 250 lacerations that did not extend above the crown, and required no operative interference. I have seen over 450 cases of internal laceration, and of over 100 that I have now operated on seventy were on the right side and thirty on the left, and uniting, that is, double lacerations.

Many of these superficial lacerations may be benefited by the application of the actual cautery and packing the parts around with carbolized or iodized cotton. I have seen very good results in quite a large number of such cases.

TUMOR OF CEREBELLUM.

BY WILLIAM WATKINS SEYMOUR, M. D., TROY, N. Y.

I WAS consulted in my office July 10, 1882, by the patient, a boy sixteen years of age, accompanied by his father, regarding intense paroxysmal headaches, which were sometimes followed by pain for some hours. The patient's health was declared to have been excellent up to three months before I saw him, at which time the headaches began. And since he has been constantly dizzy, and has staggered. The pain began suddenly, generally about one o'clock every other night, was located in the left parietal region, and was so severe that at times the patient aroused the neighbors by his screams. Vomiting always accompanied the paroxysms of pain. There was an indefinable history of three epileptiform attacks. Judging from the vomiting and tendency to fall to the left that the headaches depended upon serious cerebral disease, I made use of the ophthalmoscope and found marked optic neuritis of both eyes. Vision, however, was $\frac{1}{8}$ in each eye, and both field and color perception normal. The tuning fork to forehead and teeth showed absolute deafness of left ear. There was no paralysis of ocular muscles, and light and accommodation pupillary reflexes were normal. Knee reflex normal. Sensation unimpaired. Heart and lungs sound. Patient could stand with eyes shut, and showed no loss of coördinating power in walking. Facial expression one of hebetude, and responses to questions slow. No history of syphilis, no evidence of tuberculosis. I informed the father that in my opinion his son had a tumor growing in the cerebellum, and I saw no hope for his recovery. The growth I inferred to be a glioma be-

cause of the absence of evidences of syphilis, tuberculosis, or heart disease leading to embolus or abscess. Large doses of quinine and of iodide of potash combined with bichloride of mercury were of no service. On August 8th I saw the patient at home, he having taken to his bed two days before. The paroxysms were much more severe, and at times there was retraction of head and neck; patient felt weaker, and was dizzy as soon as he sat up; there was a tendency to facial paralysis of right side, the mouth and tongue being drawn to left; this lasted only twenty-four hours. The right arm and leg appeared weaker than the left, the grip markedly so. No disturbance of sensation. Temperature normal. Mercurial inunction and anodynes for pain ordered. Dr. Winship, of Eagle Mills, who has had an unusually large experience with epidemic cerebro-spinal meningitis, saw him a couple of days later with me, and we were agreed that the trouble was in all probability a new growth. August 19th I was discharged for a physician who regarded the case as meningitis. Patient continued to fail. Hemiplegia of right side set in, then general paralysis of all extremities, and the patient could not open his jaws. During which time I was informed by the father the diagnosis was changed from meningitis to abscess, and finally it was thought possible there *might* be a new growth. On January 23, 1883, the patient died, and I being out of town, my father, Dr. William P. Seymour, and Dr. Henry Hun, of Albany, attended as my representatives the autopsy the following day. No evidence of meningitis was found. The lateral ventricles were greatly distended. The following is from a note to me from Dr. Hun: "Projecting from the cerebellum into the fourth ventricle, and very nearly occluding the latter, was a gray, transparent gelatinous mass. This mass occupied the central portion of the right lobe of the cerebellum, and almost the entire mass of the central body of the cerebellum, the left lobe being apparently not involved. Externally the cerebellum appeared normal, but the right lobe was a mere shell inclosing a soft, jelly-like mass. The medulla oblongata was apparently normal. Pons varolii showed on section an area of dark-gray degeneration occupying the position of the right processus cerebelli ad testes." Microscopical examination by Dr. Hun showed the growth to be myxo-glioma.

CASE OF LABOR. PYÆMIA. RECOVERY.

BY DAVID DANA SPEAR, M. D., FREEPORT, ME.

ON the 10th of December last I was summoned to attend a case of labor which was the beginning of a case of much interest as well as personal anxiety, and one which may not be uninteresting to the profession. I had, fifteen months previously, attended the same patient in her first confinement, at which time there was no abnormal condition with mother or child, and everything connected with the case was most satisfactory. In her second confinement, the one of interest, on making my first digital examination the os was found but little dilated, firm and hard to the touch, and I was told a large quantity of water had escaped some hours previous, so I had in store the attention upon a "dry labor," but the head was in the first position. On the anterior part of the os tinea, pendent

and movable, was a small, smooth tumor, about an acorn's size, which between the interval of the first and second examination had disappeared, having probably ruptured during a strong pain immediately after the examination. The labor lasted some ten hours, but terminated without further accident, and without interference, and had it not been for the sequel which followed would have been remembered only as tedious. On making my complementary visit fifteen hours later the patient was in good condition, with pulse at 80, temperature 98° F., and respirations 14.

Five days later the patient had a severe chill, soon followed by rapid pulse (120) and high temperature (105° F.), with rapid respiration (30), marked dullness under right scapula. Three days later rusty sputa and all the phenomena of a frank pneumonia, which ran a regular course with favorable symptoms to the seventh day, during which the lacteal secretion had ceased, but the lochial, however, had its regular course.

Twelve days after the labor, and seven after the initial chill, pain was complained of in the left arm, which became much swollen and tender to the touch throughout its entire extent. No one place was more painful than another. Temperature 106° F.; pulse 136; chills. Ten days later the pain became most severe about the elbow-joint, at which point I found fluctuation, and with the aspirator took sixteen fluid ounces of greenish pus. The condition of my patient at once became improved, temperature, pulse, and respiration becoming nearly normal. The appetite, which before had been nothing, was now good, and I pleased myself with the vain hope that the darkness had passed, and the day of complete recovery was at hand. Idle expectation, for some ten days later there was another chill, and a rapid rise of temperature and pulse, associated with severe pain in the right leg, the warning note of more trouble. The pain, swelling, and chills were troublesome symptoms. A tape around the thigh indicated twenty-nine inches. At this time, assisted by Dr. James M. Bates, a skillful surgeon, I drew off ninety-six ounces of pus. Two days later eighty ounces more, and within the next four weeks following, at different times, I drew with the aspirator the total amount of ten quarts of pus, when at last I enlarged the opening and put in a drainage tube.

Recovery has been complete. The treatment consisted of brandy, opiates, quinine, and Frye's emulsion, the last of which was taken for a long time.

To me the peculiar interest of the case is its rarity, and the recovery from a condition of pyæmia, which according to most writers, is equally rare.

To the full appreciation of the case I ought to state that the age of the patient was about twenty-three years, that she had, prior to this sickness, always enjoyed almost perfect health, and her history developed no hereditary taints or acquired malady.

— A writer in a contemporary on the hygiene of the rectum, deprecating too great haste in the unloading of that viscus as conducive to constipation, urges "humanitarians to insist that at least one third as much time be given to unloading the alimentary canal that they take in filling the same."

— Dr. Squibb remarks in the *Ephemeris* that the term "chemically pure" (C. P.) has lost all significance as commonly applied to drugs.

Reports of Societies.

PROCEEDINGS OF THE SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

H. C. HAVEN, M. D., SECRETARY.

MARCH 7, 1883. DR. R. M. HODGES presiding.
DR. A. POST read a paper entitled

CONGENITAL DISLOCATION OF THE HIP,¹

and exhibited two patients illustrating the condition.

In the discussion which followed DR. E. H. BRADFORD said that in almost all the cases which had come under his observation, a mistake in diagnosis had been frequently made. He had seen five cases of single congenital dislocation of the hip: one boy, three girls, and one baby whose sex he could not recall. The diagnosis is especially difficult in babies; if the child is frightened it is not easy to decide as to the presence of rigidity in fat infants, or to get Nélaton's line accurately. The previous history, if carefully considered, will establish a diagnosis.

In regard to the theory of its origin, Dr. Bradford added to those mentioned by Dr. Post that of Réclus, who suggests that it may sometimes be due to a form of temporary infantile paralysis, affecting only the muscles about the hip, coming on at some period between birth and walking, and giving rise to a dislocation.

DR. E. J. CUTTER asked the reader the explanation of the foot being everted in these cases, while in ordinary dislocation upon the dorsum it was inverted.

DR. POST explained that the absorption of the head changed entirely the conditions from those of a recent dislocation.

DR. D. W. CHEEVER asked if anything was known as to the condition of the socket in these cases.

DR. POST replied that the few recorded autopsies would seem to show that the socket was gradually filled up and obliterated, and instanced one case where there were three imperfect sockets, one having been gradually formed after another as the head of the femur changed its position.

DR. CHEEVER said that he should suppose the success of treatment would depend on the presence of the original socket, to which the head of the bone might be returned. Remembering that the socket in its prenatal condition is imperfectly developed, is there any proof that nature goes on to build up a perfect socket in these cases?

DR. POST could not answer positively, but was under the impression that one case had been recorded where at some years of age there had been found at the autopsy a perfect acetabulum.

DR. CHEEVER asked how long before the head of the femur was absorbed.

DR. POST replied that it must be longer than ten or twelve years. Cases had been reported where patients of this age had been very much benefited by treatment, reduction having been accomplished and maintained. In the case of the oldest girl shown, where the head of the femur could apparently be felt, he thought good could be accomplished by treatment, that is, reduction, and retaining the joint *in situ* by some form of retentive apparatus for a long period.

DR. CHEEVER asked if there was any record of im-

¹ See page 193 of this number of the JOURNAL.

provement having been gained by treatment in double congenital dislocation.

DR. POST said such cases were reported by various French authors.

DR. N. GREEN spoke of a case of double congenital dislocation of the hip which had recently come under his notice. The walk was very peculiar, but the person, now a young lady, had always been capable of considerable physical exercise, walking, running, and even as a child climbing trees.

DR. R. M. HODGES did not think in the cases exhibited or referred to there was sufficient evidence to show that at any time, even at birth, the head of the femur was perfect, and suggested that they might be considered congenital malformations rather than dislocations. This would account for the lack of the usual signs of dislocation, and the frequent failure to recognize what it appears is not a rare form of deformity. If at any time a perfect head of the femur had existed the symptom of dislocation must have been present. Their absence would seem to indicate that this part of the femur had never been fully developed.

CONTRACTION OF THE KNEE-JOINT TREATED BY SPLINTS.

DR. H. L. BURRELL and DR. F. S. WATSON showed patients who had been treated by them for contraction of the knee-joint by different splints.

DR. A. T. CABOT showed a patient treated for the same condition by the *brisement forcé* method, the leg being incased in plaster of Paris. Their remarks, as well as those of Dr. E. H. Bradford on the same subject, follow:—

DR. BURRELL. This apparatus is one intended to straighten false ankyloses of the knee-joint. In the flexion resulting from chronic disease of the knee-joint there is a dislocation backward of the head of the tibia on the condyles of the femur and an eversion of the foot; this, of course, occurs in all degrees, from the slightest subluxation to where the head of the tibia may rest practically in the popliteal space.

To reduce this deformity two forces should be applied: one of which shall steady the condyles of the femur, while the other pushes forward to its proper plane the head of the tibia. These two forces alone, however, would cause the head of the tibia resting in one plane to impinge against the condyles of the femur which rest in another; therefore, extension to the leg and counter-extension to the thigh are necessary that the head of the tibia may glide forward over the condyles of the femur. As the deformity diminishes the eversion of the foot will correct itself.

To meet these indications an apparatus is constructed of two iron wires, one of which, extending in the line of the femur from the perineum on the inside of the thigh, is united posteriorly by a light steel band to the other, which occupies a corresponding position on the outside of the thigh. These wires extend three inches beyond the foot, then turn at a right angle downward to give a point for application of extension. These wires may be bent at the knee-joint in the severer forms of flexion.

The wires should be united over the surface of the patella and on the anterior surface of the thigh by two strong leather flaps which lace up in front. Care should be taken that the surface of the thigh be well padded, especially just above the patella; this gives the steady force to the femur.

The force forward to the tibia is gained by a plaster-of-Paris shell, which extends posteriorly from the head of the tibia half way down the leg, and half encompasses it; into its upper and lower portions should be incorporated pieces of webbing which are to be attached to buckles on the anterior wires.

The extension is obtained by strips of adhesive plaster on the leg attached to sliding buckles on the right angle turn of the wires; the counter-extension by strips extending up the thigh and attached to buckles on the posterior steel band.

This girl, a patient of Dr. E. H. Bradford's, is nine years old, and has had disease of the knee-joint for three years. She entered the Home of the Good Samaritan with her leg flexed at an angle of 110°; the patella was firmly adherent to the surface of the condyles, and the cicatrix of an old sinus existed just outside the patella; forced flexion produced but slight movement in the joint.

A splint similar to the one described was applied after patient had been in bed six weeks. The deformity was corrected in three weeks from the application of the splint. The leg and thigh were then encased in plaster of Paris, and the child went home on crutches with a high shoe on the sound leg to relieve the lame leg of all chances of pressure.

For this apparatus it is claimed that it is easily constructed and inexpensive, and that it correctly applies the forces necessary to reduce contractions of the knee-joint.

DR. F. S. WATSON. Most authorities agree that contractions of the knee-joint originate in most instances in disease within or about the joint. The class of deformities referred to are represented by more or less flexion of the leg upon the thigh, accompanied in the majority of cases by a backward dislocation of the tibia upon the femur. The two chief factors for the production of this position are:—

(1.) That flexion is the position giving the greatest capacity to the joint, and securing the least inter-articular pressure, and hence the least pain.

(2.) That the flexor group of muscles is credited with a greater strength than the extensors, and in overcoming their action flex the leg on the thigh.

Maintenance in this position finally occurs, first, by the continued contraction of the flexors; second, by the growth of more or less firm fibrous bands within or around the joint or of bony union (false and true ankylosis). Flexion is an early feature in the deformity; dislocation of the tibia and the ankylosis come on more gradually. The result is an inability, total or partial, to use the limb, and destruction of the joint's function. Hence these cases have a strong claim upon the surgeon's attention. Two methods have been for many years employed in the treatment of these cases:—

First, the sudden restoration of the limb to its normal position, by rupture of the adhesions, preceded or not by tenotomy. The method which experience and intelligence have selected as best to accomplish this is that by sudden flexion followed by extension. A large experience of this operation has shown it to be free from danger ordinarily, and it has justly been a favorite practice.

The second method may be employed when for any reason it is desirable to avoid an operation, and is that by gradual mechanical correction.

The indications for the application of mechanical

force are as follows: To reduce the backward dislocation of the head of the tibia and draw out the flexor muscles to their original length: and as an assistance to this manœuvre to pull apart the articulating surfaces of the joint. The former is accomplished by pressure properly applied against the back of the head of the tibia, acting forwards. The latter by extension on the lower leg in the line of deformity, which will always be a changing line as the leg straightens. The third indication is to fix the femur in such a way that these manœuvres can be executed upon it as a fixed body by the tibia.

These principles have all been recognized and acted upon in various ways for many years, and many ingenious apparatuses have been devised to accomplish the result. Little's, Thomas's, and Schaffer's may be mentioned as meeting the indications satisfactorily. The means which accomplished the correction in this case is one way of doing it, and is in imitation of that employed by Dr. Burrell in a case the action of which I had the opportunity of seeing.

This treatment is not preceded by tenotomy. Of course success by this procedure is not contemplated in cases of bony ankylosis.

A. M. W., aged ten. Phthisical history on mother's side; child had whooping-cough at two years. When a year and a half old was struck on the right knee by a water pail. This was followed by an acute synovitis. Some pain and swelling were still present one year later, and the limb was flexed, but could touch the toe to the ground and use the leg to walk on. For two years she continued to walk without the aid of a crutch, since which time flexion has gradually increased, until the present condition was present. Deformity has existed there for seven and a half years, and the patient has been unable to walk without crutches for four years.

Condition on Entrance. General condition good. Right knee larger over the condyle by half an inch than the left—eleven and a half inches, eleven inches. Muscles of the thigh and leg somewhat but not markedly atrophied. Patella lies over the external condyle, and is immovable. Leg can be flexed slightly; farther extension is quite impossible, the leg being held rigidly. There is no sense of grating or unevenness within the joint when the leg is moved. No points of tenderness. There is a backward dislocation of the tibia not very marked.

January 1st. Splint applied.

February 3d. Leg straight; splint removed, and leg put up in plaster.

During the treatment there was some redness about the joint and considerable pain for a time.

Dr. A. T. CABOT showed a girl six and a half years of age whose knee he had recently straightened. The disease which caused the contraction began three years ago. In August, 1882, she entered the Massachusetts General Hospital with the knee strongly flexed and free from pain. It was straightened by gradual extension, and she was discharged September 23d with the leg in good position.

January 22, 1883, she reentered the hospital with the knee strongly flexed and immovable by any moderate amount of force. The patella was fixed.

February 9th. The child was etherized, and with a considerable exercise of force the leg was partially straightened and put on a ham splint. By the advice of Dr. Hodges, the complete straightening was left for

a subsequent operation. The patella could not be loosened from its adhesions.

February 20th. The child was again etherized, and the knee yielded easily, coming into good position. A plaster bandage was at once applied, and the leg was fixed in about the position it would assume on a slightly curved ham splint. The child suffered no pain after the operation, and was running about the ward on the second day.

Dr. Cabot called attention to the value of this operation in cases where, owing to tuberculous tendencies, it is unwise to confine the patient long in bed.

In addition to the cases reported by Drs. Burrell and Watson, Dr. BRADFORD reported the following case:

W., girl, nine years old, with chronic disease of the knee-joint of four years' standing, without suppuration, with some enlargement of the femur, and a puffy condition of the soft tissues of the joint. The patient had had attacks of pain which had rendered the limb useless for months, but had recovered so as to be able to walk on the limb with only occasional and temporary pain. The limb was badly contracted at the knee, so that the leg formed nearly a right angle with the thigh. There was no ankylosis, there being slight movement at the joint. The patient's surroundings and family history were good.

Various attempts were made to correct the deformity, but without success. In November the appliance described by Dr. Burrell was employed, and by the last of January the limb was practically straight. At this time if the patient sat upon the floor with the leg kept as straight as possible, but without pressure upon the knee to hold it down, the space between the floor and the popliteal space was one and a half inches.

A fixed appliance was then put on. The case differs from those just mentioned in that the patient was allowed to go about during the treatment, and was not kept in bed a single day; the child used crutches, and the foot on the well side was raised so that the affected limb should swing free of the floor. The complete correction was delayed by the fact that the parents were inclined to loosen the straps at night whenever the pressure appeared to be at all annoying to the child. No opiates were required, but for the first two weeks the child seemed to be troubled by the constant pressure.

But little gain in the correction of the deformity could be noticed until the third week of treatment.

Dr. Bradford thought that the appliance devised by Dr. Burrell had certain manifest merits; it is light, cheap, easily attended to, and easily made. It is not so clumsy as that used by Little, and without being less efficient allows the patient greater freedom. It is much less complicated than the splint recommended by Dr. Schaffer. The pressure backward and forward necessary to correct the deformity can be more easily regulated in Dr. Burrell's splint than in the simple apparatus used by Thomas, of Liverpool.

This latter appliance, though rather clumsy, is of help in the correction of this distortion, as Dr. Bradford had had an opportunity to see in two cases; one, a girl of twelve years with a contraction of the knee of two years' duration; the second, a girl of ten. In this latter case the limb recontracted in about two years, owing to a subsequent injury and neglect of the splint in after treatment.

It is manifest that mechanical treatment is not feasible in all cases of this sort. It demands for success a

certain amount of attention on the part of a nurse and a certain amount of time. If these cannot be obtained forcible measures are to be preferred.

Dr. Bradford reported seven cases of forcible straightening for right-angled deformity of the knee-joint following chronic disease of the knee. Tenotomy was done in all of these, and the limb was fixed immediately after the operation. The patients ranged in age from twenty-four to two years, and the affection was in various stages of development, from that of a subacute inflammation of a few weeks' duration to that with firm fibrous ankylosis which had lasted for years. In the child of two, an open sinus was present. In a boy of fourteen, separation of the epiphysis at the lower end of the femur occurred during the straightening; union took place, however, readily, and a useful limb resulted.

The practice in these cases differed somewhat from that recommended by many authorities: (1) in fixing the limb in the straightest possible position immediately after tenotomy, instead of waiting a few days for the wound by the tenotome to heal; (2) in securing the limb in a fixed dressing immediately after the straightening.

It is a well-established fact that the main check in the attempt to straighten a well-marked contracted knee is not the muscular contraction but the deep fascia and posterior capsule.¹ Under an anæsthetic a limb can be forcibly held much straighter than is possible without anæsthesia, and it saves the patient time and annoyance if what is gained in this way be kept. This can be done without discomfort to the patient by fixing by means of plaster-of-Paris bandages, provided they are applied so as to exert an equal pressure over the whole limb, and provided the limb is well held while the plaster splint is applied and until it is hard. Of the seven cases mentioned a plaster bandage was used as an after-dressing in all except that of the patient twenty-four years old, where a ham splint was used; this was loosened, however, on account of the pain occasioned and the result was not as good as in the other cases, where a plaster bandage was applied, which seemed to occasion much less pain as well as to give better fixation.

A general discussion followed on the merits of the different materials for a stiff bandage.

Recent Literature.

Second Annual Report of the State Board of Health of New York. Albany. 1882. 726 pages.

First Annual Report of the State Board of Health of New Hampshire. Concord. 1882. 318 pages.

First Annual Report of the State Board of Health of Arkansas. Little Rock. 1883. 181 pages.

Our neighboring States of New York and New Hampshire, together with the State of Arkansas, having wheeled into the line of States which have established boards of health, the latter being the twenty-eighth and last of the list, have issued their Annual Reports.

The New York Board is composed of nine members, three of whom are appointed by the Governor, with the advice and consent of the Senate, and are entitled Commissioners of Health, three are appointed by the

Governor alone, and are selected from the Commissioners of Health of Cities, and three are *ex officio* (the Attorney-General, the Superintendent of State Survey, and the Health Officer of the city of New York).

The act establishing the Board has in general the provisions of the Massachusetts act of 1869, with certain exceptions.

Section 8 provides that the Governor may require the Board to examine and report upon nuisances affecting the security of life and health. It also provides that the Governor may order the abatement of such nuisances, fixes the penalty of neglect to comply, and also makes provision for the execution of the order.

The first fifty pages of the report contain a summary of the work of the Board, followed by an abstract of its transactions, a report of its finances, and of the Committee on the Registration of Vital Statistics. The work of registration in New York is hardly begun. Previous to the appointment of the State Board of Health there was no system of registration of vital statistics except in six cities.

Investigations of prevalent diseases, notably of small-pox, diphtheria, and typhoid fever, in special localities follow, and also several papers relating to the prevalence and the control of contagious diseases, which were issued as circulars for public distribution.

The report of the Standing Committee on Public Institutions is devoted entirely to the sanitary condition of the school-houses of the State, and of the million or more of their occupants. For this purpose the Board have availed themselves of the valuable assistance of Dr. D. F. Lincoln, who devoted his time and attention for several weeks to the school-buildings in ten counties and eight cities. The subjects of investigation have been (1) heating and ventilation; (2) lighting; (3) size of rooms; (4) desks and seats; (5) drainage, sewerage, and plumbing; (6) state of repair and safety; (7) wardrobes, water supply, and personal cleanliness; (8) school hours; (9) vaccination and prevention of contagious diseases; (10) criticism of plans of school-houses, etc.

A brief synopsis of replies to inquiries is given. Dr. Lincoln's report on School Hygiene deals mainly with the subjects of ventilation and of lighting, and is amply illustrated with diagrams of school rooms, showing faulty and model systems of ventilation and lighting.

Dr. Agnew contributes a paper on an Epidemic of Contagious Ophthalmia in a State Institution, in which the disease was believed to have been due to imperfect quarantine, bad lavatories, overcrowding, bad food, and bad drainage.

The importance of thorough quarantine to the people of New York, and through them to the rest of the United States, cannot be overestimated when it is borne in mind that a half million people arrived at the port of New York in 1881, and a greater number in 1882, to be distributed throughout the Republic.

This portion of the report comprises a brief historical summary of the subject of quarantine, accounts of special cases and regulations of the National Board as to contagious diseases. Of the two principal diseases subject to quarantine laws, yellow fever and small-pox, the latter with its kindred subject, vaccination, claims the chief share of attention. The opponents of vaccination will find little consolation in the following statement: "It has been estimated that not one case in 100,000 vaccinations (of immigrants) with bovine virus has been attended with unpleasant results. The

¹ Swain, Knee-Joint, page 55, for a pathological proof of this fact.

records of the Vaccine Department of the New York City Board of Health show that in seven years previous to January 1, 1882, 101,420 primary vaccinations and 343,708 revaccinations were made without results prejudicial to health which were justly chargeable to vaccine influence.

The report of the Committee on Drainage, Sewerage, and Topography contains the results of their investigation in certain localities, and recommends the following subjects for future work:—

(1.) What is the best plan of a separate and most economical system of sewerage for villages and small cities, and by what methods shall the outflow of the storm-water and the soil drainage of such places be secured?

(2.) How shall the ground drainage of building sites be secured for separate dwellings and villages?

(3.) What provisions are to be required in a general drainage law?

(4.) What other preliminary work as to sanitary drainage should be done by the State, and what responsibility should be required of the State Board as to projects of general drainage?

The first of these topics is answered by the special report of Dr. Gardiner, the Superintendent of State Survey, who treats of the advantages of *dry removal* and of the pail system, of water carriage and of separate sewerage. The report of Mr. Latrobe to the city of Baltimore on the Memphis system is recommended in terms of unqualified praise.

That the Board stand committed to the separate system of sewerage is evident from the eighth clause of their resolutions, page 335:—

"The separate system of sewers with flushing tanks is hereby recommended for general use in the State."

The report of the Committee on Effluvia Nuisances deals chiefly with the condition of certain manufactories on Newtown Creek, a locality where the number and variety of stenches cannot be excelled in America. Upon this stream, a short distance only from the populous parts of New York City and Brooklyn, are located petroleum refineries, fat rendering works, superphosphate works, manure dumping grounds, tripe and gut works, varnish factories, gas works, *et id omne genus*. Generally the operations of those works appear to have been conducted in a slovenly and offensive manner. The worst nuisance with which the Board has had to deal is the "sludge acid," or the spent sulphuric acid used in the refining of petroleum, and loaded with all the disgusting sulphureted vapors, vast quantities of which are daily let loose into the tidal waters of New York and Brooklyn.

The thorough and well-nigh exhaustive researches of Dr. Ballard in England show that it is for the interest of the manufacturer to arrest the offensive exhalations from such works.

The final portion of the report includes the reports of the Sanitary Committee on the following subjects:—

(1.) The chemical examination of drinking waters.

(2.) Methods and apparatus for testing inflammable oils.

(3.) Report upon adulteration of food and drugs.

The report upon food and drug adulteration comprises the final two hundred pages of the report, and is a valuable contribution to the literature of that subject. The law of New York is similar to that of Massachusetts, the amount appropriated for its execution being much larger. The work of inspection and anal-

ysis is distributed among several analysts in different portions of the State.

The report is especially valuable for the full bibliographical lists which are appended.

The First Annual Report of the New Hampshire Board contains articles upon the following subjects:—

(1.) The Secretary's report, dealing chiefly with the subject of small-pox in New Hampshire in 1881-82, and the pollution of the Ammonoosuc River.

(2.) Vaccination, being a reprint of Dr. Lindsley's excellent article published in the Fourth Annual Report of the Connecticut Board.

(3.) Ventilation, by Dr. G. P. Conn. A practical statement of this important subject, and especially valuable as based upon the writer's own experience.

(4.) Suburban School-Houses, by W. R. Briggs, Esq., of Bridgeport, Conn.

(5.) Adulteration of Food, by Dr. E. J. Bartlett.

(6.) Water Contamination, by Dr. A. H. Crosby.

(7.) State Medicine in Germany, by Dr. C. H. Horsch.

(8.) Common Law relating to Nuisances. Citations.

(9.) Registration Report.

The First Annual Report of the Arkansas Board contains the Act establishing the State Board of Health, which is similar in its provisions to that of other States. Also the records of the transactions of the Board, with circulars relating to epidemic diseases, etc.

Laws regulating the Registration of Vital Statistics, which do not appear to have been generally complied with.

Reports or Addresses of the President of the Board upon various health topics.

Statistics and Reports as to Small-Pox, from which it appears that in Little Rock there were seventeen cases of small-pox in 1882, nearly all in public hotels. Two cases resulted from the breaking down of a vehicle in which the body of a small-pox patient was being conveyed to a cemetery. Of these seventeen cases thirteen had never been vaccinated, and nine of the thirteen were fatal.

Such statistics, though meagre, are valuable as confirming the accumulated evidence of the past century as to the efficacy of vaccination.

Our own excellent system of registration in Massachusetts might be still farther perfected by a law requiring every physician who is called to give a certificate of death in a case of small-pox to state whether the deceased had or had not been vaccinated. Such a bill was prepared during the session of the Legislature of 1883, but owing either to the neglect or opposition of an inefficient public health committee no action was taken upon it.

A brief report on an outbreak of choleric disease in a hotel in consequence of a neglect of sanitary precautions as to the proximity of the public well to the water-closet.

The publication in a State document of the sensational report of the American Public Health Association as to the prevalence and prevention of venereal diseases is a matter of doubtful propriety.

The remainder of the report is mainly statistical, and consists of meteorological and vital statistics of a few cities and large towns.

— *In vino veritas* is amended by the enterprising druggist into *in soda sanitas*.

Medical and Surgical Journal.

THURSDAY, AUGUST 30, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number: \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

COLLECTIVE INVESTIGATION.

WE took occasion when the subject was first under discussion to draw the attention of our readers to the plan for the collective investigation of disease of the British Medical Association. The object of the movement is the collection of the scattered observations of such members of the Association as feel inclined to join in the movement. The suggestion to combine the observations of many has attracted very wide attention, and propositions have been already made in other countries for similar investigations. The subject was brought before the American Medical Association at its last annual meeting by Dr. Billings, and was referred to a committee of which Dr. Davis, of Chicago, is the chairman, but so far as we know no definite action has yet been taken towards carrying the idea into active operation. The subject has been brought before the Berlin Medical Society, and committed to a committee which contains among others the well-known names of Professor Frerichs and Drs. Leyden, Fränzel, Ewald, Jastrowitz, Löwenstein, and Börner. The plan of the Collective Investigation Committee having the matter in charge for the British Medical Association has been to issue memoranda on several subjects for inquiry, and to issue with them cards of questions to be answered. Such memoranda have been issued on acute rheumatism, acute pneumonia, inherited and acquired syphilis, diphtheria, and the question of the contagiousness of phthisis, and the first report of the committee has been already issued, and lies before us. This report is in a measure preliminary, but it is evident that the method of studying the phenomena of disease proves attractive to a large body of the British profession. Rarely has so much time and effort been freely given as by the various members of the committees in the hope that the profession at large would appreciate and respond to their efforts. When we repeat the announcement of the committee that they have already in hand sufficient material to more than fill another such volume as the present, and the returns are rapidly accumulating day by day, it will be abundantly evident that their efforts meet the response desired.

The present volume is edited by Professor Humphrey and Dr. Mahomed, and contains the addresses of Sir William Gull and Sir James Paget, which were delivered as a means of encouraging the movement at its inception, and serve as an introduction to the present report. The greatest space is taken up

by a report on the contagiousness of phthisis, of which we speak more at length in another place, our object at present being simply to note the general progress of the movement. Preliminary reports on acute pneumonia, chorea, acute rheumatism, and diphtheria follow. The volume also contains reprints of the memoranda and questions issued on the other subjects. The report shows that the chief aim of the investigation so far is the collection of simple facts to which any physician of large practice may contribute, and it is made evident that the system is capable of producing results sufficient to justify the efforts that have been made.

"THRIFT, THRIFT, HORATIO."

A NEW departure in the medical business has been inaugurated in a town not many miles from this city by a young man who has issued his prospectus to the inhabitants, as follows:—

"A young physician, graduate of a regular medical college, having about three years' experience in hospital and private practice in the Ohio Valley, is desirous of locating in this section. Being obliged to earn a livelihood for himself and family, and at the same time knowing the slowness and difficulty of obtaining a practice in the ordinary way, offers [*sic*] to contract for your patronage at the following unprecedented terms:—

"Single persons five dollars per year.

"Entire families, three dollars per year for each member.

"Surgical operations and labor cases extra, at reduced rates, payable quarterly in advance.

"He also agrees to visit you at least once every week, unless called upon to treat you for some sickness requiring more frequent attendance. This will give you the advantage of medical advice in many cases about which persons do not ordinarily consult a physician. He will frequently, also, be enabled, by this arrangement, to ward off a serious attack of sickness by timely treatment.

"For further information apply to ———, M. D.

"Or leave your address and he will call."

Only one or two possible difficulties occurs to us in this arrangement. The contract price per quarter in advance for surgical and obstetric assistance is not specified. It can hardly be one price for all, because the elderly spinsters will never pay the full of this extra fee, half of which presumably goes for midwifery attendance. No, there must be a sliding scale, arranged according to the contractor's estimate of the number of surgical operations and deliveries that he will be called upon to perform for the individual in question during the quarter. And even then there may be trouble; for having paid for a confinement during the given quarter a matron may insist on delivery of the goods; or a man may decide to anticipate all the surgery he will need in a number of years during the quarter that he is "taking" of the practitioner. Furthermore, on the other hand, if the young physician is an enthusiast in his profession he may insist that his contract to do all manner of surgical operations for a man during a given period carries with it a right as well as an obligation, and may thereupon proceed to go through the catalogue of operative surgery, the patient *volens volens*.

With these trifling queries as to minor details we welcome the plan of the young man from Ohio as thoroughly original and comprehensive. It takes off fictitious and inflated values, and puts his services at

a fair compensation. If he will furnish his own medicines the public cannot afford to do without him. The stipend is by no means exorbitant. At the utmost it can never be more than a fraction over nine cents per visit, even to a "single person," and in case the patient should be taken sick, especially if he be a family man, it is liable to fall to a really very modest figure. Add to this the attraction of a weekly social call, and even to the single person, to whom this luxury comes highest, the inducement may be fairly considered "unprecedented."

A REPORT ON THE COMMUNICABILITY OF PHTHISIS.

IN the last issue of the JOURNAL an abstract was given of the laws which were passed in Naples toward the end of the last century at the instigation of its Sanitary Council to control the spread of phthisis by infection, and in another editorial article a brief account is given of the general methods and aims of the Committee on Collective Investigation appointed under the auspices of the British Medical Association at the instigation mainly of several earnest enthusiasts, among whom may be mentioned Professor Humphry, of Cambridge, and Drs. Mahomed and Ransome. Among the interesting and instructive papers contained in the Collective Investigation Record of July, 1883, the longest and most important is a Report on the Communicability of Phthisis, some of the details of which we take much pleasure in reproducing, especially in continuation of the subjects spoken of in our last number.

The sub-committee appointed to draw up this report consisted of Drs. Dyce Duckworth, Taylor, Tyson, Burney Yeo, and Mahomed as secretary. Last January they addressed the following questions to every member of the British Medical Association: (a.) Have you observed any case or cases in which pulmonary consumption appeared to be communicated from one person to another? Answer "yes" or "no." (b.) If more than one case observed, say how many. (c.) If any case or cases have been observed give any brief particulars you may think worthy of record, noting the following points: (1) the date of the observation; (2) the relationship, if any, between the individuals concerned; (3) the presence of family predisposition to the disease. It should be particularly noted whether the disease had occurred in the parents, grandparents, and other relatives, or only in the brothers or sisters of the person to whom the disease was communicated.

Simultaneously an article was inserted in the Association's *Journal* setting forth the scope and object of the investigation with a brief account of the history of the inquiry by previous investigators. The committee deemed it advisable that their first effort should be a very simple one, that the initiatory questions should admit of immediate and ready answers, and that it should be left to the observers to answer them in their own fashion, and it could then be easily seen, they thought,

whether the subject was one which might be pursued further and in a more systematic manner with advantage. In this address the word "contagiousness" is made synonymous with "communicability," and the question becomes, Is phthisis communicable under *any* conditions, and if so, under what? The address further gave a brief synopsis of the inquiries of previous investigators, among our own countrymen mention being made of Drs. Bowditch, Da Costa, Solis-Cohen, Stillé as in favor of contagion being a cause, and Dr. Rush as denying it. The figures of Dr. Holden, of New Jersey, are not mentioned.

The committee received 1078 returns to their circular. Of these returns 673 were simply negative, showing that no case had been observed by the member making the return, but expressing no opinion. Such returns were set aside, as admitting of no further analysis. The remaining answers, containing observations of some kind, were classified as follows:—

Class 1. Affirmative observers	261
Class 2. Doubtful observers	39
Class 3. Negative observers	105

The returns in Class 1, containing the affirmative observations, were subdivided into groups, according to the nature of the relationship between the victims. Thus 158 of the affirmative returns refer *exclusively* to cases observed between husband and wife, and communication between husband and wife is mentioned in 34 of the remaining returns. In 119 of these cases it is stated that the disease was transmitted from husband to wife, and in 69 from wife to husband; and it is distinctly stated in 130 of these cases that there existed no family predisposition to phthisis in the partner to whom it was supposed to be conveyed. The ratio corresponds in a general way with that resulting from previous inquiries.

In a relatively great number of the cases of communication a very rapid course of the disease was noted.

The returns are published in full or abstract as an appendix to the committee's report, and comments are made in the text on quite a number, for which, as well as for a further analysis of the returns, our readers would do well to consult the original report when possible.

One fact, the committee think, these returns — in common with former ones — seem to establish beyond any question, and that is, that if phthisis is a communicable disease it is only so under circumstances and conditions of extremely close personal intimacy, such as persons sharing the same bed or the same room, or shut up together in numbers in close, ill-ventilated apartments. And in conclusion of their report a hope is expressed that their returns will be of considerable value in addition in leading to more open-mindedness in the discussion of disputed questions of experience and observation.

It seems perfectly clear, from a consideration of the evidence here collected, the committee thinks, that many observers of undoubted capacity and trustworthiness have observed cases which it has never fallen to the lot of many others to encounter.

It is, perhaps, equally certain that many observers

of equal ability and carefulness have been led to draw different inferences from the observation of the same facts, and these differences of opinion may probably in many instances be traced to the existence in their minds of pre-accepted pathological doctrines.

Nothing could show more conclusively the value of *collective* investigation as opposed to *individual* impressions.

MEDICAL NOTES.

— We have often mentioned the Sea-Shore Home at Winthrop, which receives, and cares for, each summer a certain number of children afflicted with the summer digestive diseases, as a most interesting and praiseworthy charity. We believe it to be an important element in diminishing the death-rate of children in Boston during the summer months. It is dependent for existence on annual contributions, and its claims upon the charitable are annually set forth in its reports and the daily press. We are glad to see that it has been the recipient of a benefit in the shape of a grand concert and ball at Nantasket. The home is capable of using judiciously a much larger sum than it has ever had at its disposal.

— A correspondent of the *British Medical Journal* writes thus of the antagonism of strychnia and prussic acid: Some years since it became necessary to destroy an old dog. A large dose of strychnine was administered in bread, but the poison did not act very rapidly, and, as the animal's struggles and pains were distressing to watch, some hydrocyanic acid was poured in his mouth to complete the poisoning and hasten the end. To our surprise, the animal at once improved, and eventually recovered. I had forgotten this until the other day, when one of our cats was found dead in the garden, and the other dying, with all the symptoms of strychnine-poisoning, namely, constant tetanic spasms, and dilatation of the pupils, and insensibility to light. The cat was held firmly, and three or four drops of hydrocyanic acid dropped carefully on the tongue. An improvement was shortly visible; the pupils of the eyes became normal, the convulsions became less and less severe, and in a few hours the cat was all right again. I would add that the cat was nursing a kitten, which apparently suffered no inconvenience from the poison.

— The latest contribution to the sea-sickness discussion is the remark of Henry Ward Beecher, who, in referring to his trip to Europe, says he agrees with Dr. Thomson, who said, when he came on deck, that the ocean looked like one vast dose of ipecac.

— A Western contemporary recently spoke somewhat despairingly of the sanitary situation in the city which it represents, believing that the possibility of epidemic visitation during the coming season, and the lack of either municipal or State Board of Health, justified a protest. But it hastened to add: "However, we much prefer no board at all to one composed of saloon-keepers and members of the criminal classes. We want men of education and more than ordinary intelligence to compose this most important of all

municipal boards. Let the bummer element be represented elsewhere." But before this lament was published, almost before it was written, the city fathers proceeded to erect a bulwark against the cholera, in the shape of a board, constituted, our contemporary remarks, as follows:—

"Its members consist of five saloon-keepers and one poor, blear-eyed quack doctor, who advertises to cure the opium-habit and restore lost virginity, and wears a chronic blush on his nasal organ. Just why so much medicated wisdom was injected into that board is beyond our ken. "Our boy says it's all right; the cholera is coming and that will make business good for the doctors. The five saloon-keepers can outvote the other fellow every time, while they will have the advantage of his advice and operative skill in case their virtue is assailed."

— The JOURNAL is in receipt of a communication which describes a patient as having received a wound in the *lumber* region. As the individual in question is a resident of Maine we are in some doubt as to how to interpret the statement.

— Professor Neumann, of Vienna, has recently inoculated several monkeys with the secretion from indurated chancres, and has also inserted portions of chancres beneath the skin of these animals. The results in all cases have been negative; neither local nor constitutional symptoms were produced. Inoculations with syphilitic products were also made upon two horses, a pig, and a martin, all of which were unsuccessful. These results of Neumann are in contradiction to the researches of Klebs and Martineau, who in the past year or two announced that they had succeeded in communicating, by inoculation, syphilis to monkeys. — *Wiener Med. Wochenschrift*, Nos. 8 and 9, 1883.

— A rowing man who wished to exchange his adipose tissue for muscle, says an irreverent English paper, went to a well-known physician up river for advice. "Do you eat butter and fat?" asked the leech. "Yes," said the client. "Well, you must knock off that," returned the doctor. "Do you drink beer and spirits?" continued he. "Yes." "Then you must knock off that." "Do you smoke?" inquired the medical man, feeling for his stethoscope. "Yes," said the oarsman. "Then you must knock off that." "What is your fee?" inquired the athlete. "Two guineas," murmured the medical man with a faint smile of expectation. "Well, you must knock off that," said the candidate for Henley honors, as he seized his hat and made way for the next patient.

— A child, in St. Paul, Minn., nine years old, that had been in poor health for some time, was put under the care of a female practitioner in St. Paul who styles herself a "magnetic healer." At that time the child had been seized with pains in the back and the limbs, which the "healer" diagnosticated as "sciatic rheumatism." Soon after this the child was found to have fever, and a rash made its appearance — "an eruption of the blood," said the "healer," caused by the "strong medicine" employed before the patient had come under her care. She gave an encouraging

prognosis, and persevered with her treatment. Before long the family and the neighbors bethought themselves of small-pox, and asked the "healer" if it might not be that disease that the child was suffering from. On being asked this question the woman professed to consult the spirit of a doctor who, she said, had been dead several hundred years. The spirit having assured her emphatically that her patient's sickness was not small-pox, she informed the family to that effect, and repeated her cheerful prognosis. Nevertheless the child grew worse steadily, the family became dissatisfied, and when at last a nineteenth century physician was consulted the disease was found to be confluent small-pox. All this happened in a large boarding-house, in which ten persons contracted the disease, three of whom died.

Correspondence.

MEDICAL SUFFERERS BY THE FIRE AT VINEYARD HAVEN.

MR. EDITOR, — Let me beg you to put an appeal into the Boston Medical and Surgical Journal, asking the profession to aid *such members of the Massachusetts Medical Society* as have been sufferers by the recent fire in Vineyard Haven. I know personally that one member of the Society who has been a hard worker both in medicine and in the collateral sciences has lost his office, his library, and his whole stock of drugs, the last alone being of the value of five hundred dollars.

Please let subscriptions be sent to the JOURNAL. Were I to be in town I would take charge personally, and save you the trouble.

Cordially yours, E. WIGGLESWORTH.

The editor of the JOURNAL will most gladly receive any contributions for so worthy an object, and sincerely hopes Dr. Wigglesworth's appeal will meet with a liberal response.

RHEUMATISM IN THE HORSE. TREATMENT BY SALICYLATE OF SODA.

MESSESS EDITORS, — A few weeks since my horse returned to the stable after his day's work apparently in perfect condition. On the following morning he was found to be quite lame, and seemed to be suffering very much. The left hind fetlock joint was swollen, hot, and tender on pressure, the inflammation also affecting the tissues over the pastern bones down to the hoof. Movement was evidently quite painful, the animal bearing but little weight on the foot involved. The swelling, heat, and lameness increased, extending half way up to the hock. As he stood in the stall the foot was set forward most of the time, so as to diminish as far as possible the tension over the pastern bones; flexure at this part, when the limb was raised, seeming to cause no special discomfort. As the inflammation progressed the horse stood a good deal of the time with the heel raised, so that the front edge of the hoof only touched the floor, and at times was clear of it, his whole weight resting on three legs. There was entire loss of appetite.

The routine stable treatment in such cases was employed for four days (such as hot fomentations at first, followed by cold-water bandages) without relief, the

case in fact growing worse all the time. As the symptoms looked more like those of acute rheumatism than anything else I determined to try salicylic treatment. Taking the weight of the animal as a rough guide for the dose I decided to give him six times as much as a minimum dose for a man, and accordingly administered a drachm every two hours, beginning with two drachms. The most marked improvement appeared during the first twenty-four hours, at the end of which he had taken an ounce of the remedy. The heat, swelling, and pain were obviously less, and he stood with his heel down, although favoring the limb occasionally by advancing it a little before the other. The treatment was repeated, and a second ounce of the salicylate given in the course of the next twenty-four hours, with continued rapid improvement. At this time he stood in the stall with his hind feet side by side, bearing equally upon them, and when led out showed very little limp. I did not think it necessary to go on with the remedy, as all the symptoms steadily improved, his appetite rapidly gaining, so that in a day or two he bore considerable walking exercise outside of the stable, with scarcely a trace of lameness to be detected. Some swelling remained, however, for some time after, but the horse was in full use again within ten days of the commencement of the salicylate treatment, apparently as well as ever.

I am not informed whether salicylate of soda is ever given by veterinary surgeons in such cases, but the effect following its use in this case was quite as striking as when it is employed in human rheumatism. It was administered without difficulty by means of a spoon. On another similar occasion I should give it earlier and in a larger dose. There was none of the sweating which generally follows the use of the drug in the human subject.

S. L. ABBOT.

Miscellany.

CEREBRAL TUMOR MISTAKEN FOR HYSTERIA.

IN *Brain* (July, 1883,) an instructive case is described by Mr. Bruce, in which the symptoms were such as to lead to a diagnosis which was negated by the autopsy. The patient was a single woman, aged forty-five, a nurse. Had been well till 1880, cheerful, kindly, and a good nurse. Early in 1881, after taking care of a very restless child, she began to show signs of nervous trouble, was excitable and uneasy. A small tumor was removed from the breast, pronounced on good authority, after microscopic examination, to be benign. This was in June, 1881. The wound healed perfectly in four days. For a time after the operation she was very well. In August she began to grow very selfish, irritable, and jealous of her sisters; she would take fits of laughing and crying (especially the latter) for no apparent reason, and for a time she became so passionate as to be almost unbearable at home. In September, however, she was able to take a situation as a nurse, and for some nine months she seemed in perfect health. She had charge of a very delicate child that needed constant night attendance, so that for about nine months her sleep was constantly broken. In June, 1882, she began to get excitable, and to quarrel without cause with her fellow-servants; complained constantly of pains in the back, abdomen, and about one ovary, for which no local cause could be detected, and which were at the time considered hy-

terical. Finally her excitement became so great that she alarmed every one by rushing about the house at night screaming, and it was only by firm moral treatment that she could be induced to exercise self-control. She was seen by two physicians, who were of opinion that her case was one of hysteria, and recommended her removal to her own home. During one of her excited turns the first "fit" occurred, and she was said to have rung the bell to summon a fellow-servant to witness it. With rest at home the excitement passed greatly away. At the next period, in August, the second fit occurred; at the third, which occurred a week before time, and was excessive, a third "fit." Since this very slight ones had occurred three or four times on some days, and sometimes at night. She always knocked her sister up to see those at night, and those in the daytime were stated never to occur in the presence of certain friends, and always before certain others. One occurred during the author's first examination of the case, in September, 1882, and was said by patient and her sister to be quite similar to the others. She felt its onset, said, "There's one coming," grasped the doctor with her right hand, shut her eyes, threw her head back, arched her back a little. There was a slight trembling of the body, but no vaso-motor change nor frothing at the mouth. She answered a question put to her, showing (what she afterwards stated positively) that there was no loss of consciousness. The whole lasted for about thirty seconds, and was followed by no headache or any symptom except slight numbness, which passed off immediately. The "fit" did not seem epileptiform, but such as one sees frequently in hysterical subjects.

Though the history and behavior strongly suggested hysteria, careful search was made for evidence of intracranial lesion. There was found absolutely no alteration of sensibility of general or special sense (smell and taste were, unfortunately, not examined). Vision and accommodation good in both eyes. No hemiopia. Pupils equal, active, and of medium size. No ptosis; no strabismus. Ophthalmoscopically fundus healthy; no sign of past or present neuritis. All the reflex functions—tendon, skin, and organic—were normal. There was no headache, and patient said never had been. (Post mortem it was learned that she had, in June, complained of throbbing in the head.) No scalp percussion tenderness. Intellect clear; articulation unimpaired; could converse apparently without effort. Memory good. Her manner was excitable, and facial expression strongly suggestive of the hysterical temperament. Tongue slightly furred; slight constipation. Patient stated that she had never vomited. Otherwise no abnormality detected. There was no sign of, and no reason to suspect, syphilis.

Gross intra-cranial lesion being excluded, the diagnosis of hysteria was made, and in the middle of October, the fits having almost wholly ceased, except in the presence of certain friends, she was sent into the country on account of showing passionateness and jealousy toward other members of her family. There she seemed well, and wrote letters legible and well expressed. On November 17th she had a fit, the first since going to the country, and called a servant to witness it. That evening she became unintelligible, and talked nonsense. Two days later (November 19th) she was seen lying in bed; mouth to left; left occipito-frontalis weaker than right; slight convergent strabismus; weakness of right hand; legs equally strong; no

ptosis; pupils equal, active, of medium-size; no optic neuritis; sensibility, general and special, unaltered; speech peculiarly altered; no ataxic aphasia. Some leading questions correctly answered, to others an expression of stupidity, supposed at the time to be simulated. After the physician was gone she got up, walked for an hour, and made her bed without any impairment in the use of the right hand.

Next day in consultation no strabismus was found, *no twist of the mouth, no inequality in the two occipito-frontales or in the strength of the two hands or legs.* The grasp of the hands was fairly strong. The tendon and skin reflexes were, perhaps, slightly exaggerated, but equal on both sides. So far as could be judged, sensibility to touch, pain, temperature, on either side, was unaltered. Watch heard with right ear at one yard, with left at one yard and a half. The speech had still the same peculiar character, not easily described, but which suggested that she could answer when she liked, and when she did not know what was the proper answer to give she "hedged" or shammed to be stupid; thus she answered leading questions at once, and when asked on which leg she felt the prick of a pin best she said, "It's not so well on that leg as it's worse on the other." Her other remarks were somewhat similar. She seemed in all cases to understand the questions.

She was then ordered to the infirmary, but on the following day seemed quite well, said there was nothing the matter with her, and that she could be treated at home. Later she had a relapse, became violent, and struggled with her sister, showing no signs of weakness. At the visit three days before her death she was sitting by her bedside, with a stolid expression; otherwise she looked well. On being asked, "How are you to-day?" she answered with a rude stare, "Have you been sleeping?" and similarly to one or two other questions. It could not be determined whether she understood the questions, or whether she took this means of preventing any conversation. Some time afterward she looked as if she had discovered that she had made some mistake. She could walk quite well.

The resident physician adds that while she was in the infirmary for the first few days she seemed quite well, only hysterical, would not do what she was told, could only be induced to do light work, such as dusting the tables, and when the nurse was by her side, and did so then in a careless, indifferent manner, desisting the moment her back was turned. One day she vomited and spat into her soup, which she did not like; was supposed to have done this in order not to have to take it. When scolded for this did not repeat the offense except once, on the Saturday before death, when she spat into her tea. On admission talked quite correctly to the doctor and the staff nurse, would not do so to a probationer; after a few days began to be confused at the end of a sentence, would transpose words in a sentence, saying "Fine—the day," for "It is a fine day." Two days before death she frequently used wrong words, for example, "jube" for "hospital," and "a pair of legs" for "two pills." On the day before death her father did not observe anything remarkable in her speech. Once or twice she answered rudely, as it seemed, but on being checked for it gave correct replies. When asked to write what she wished her writing was unintelligible. She seems generally to have understood what was said to her,

and carried out complicated directions correctly. Two days before death, after being warned by the other patients that the nurse would be angry because she spat into her tea, and poured it on the floor, she went for a cloth and wiped it up. The day before death, at the morning visit, when told to arrange her hair, which she had left hanging about her shoulders, she did so at once. Two days before death she dragged sometimes one and sometimes the other foot slightly, and vomited once (next day, the 3d of December) quite suddenly when asked to walk round a table. During the night she did not sleep, but got out of bed often, folded and unfolded her clothes.

December 4th. On getting up in the morning she slipped to the ground, became unconscious, and, on being put to bed, remained as if sleeping quietly for four hours. Half an hour before death breathing became stertorous, and pulse could not be counted. There were no convulsions.

The autopsy showed a tumor extending from the left temporo-sphenoidal lobe to the junction of the anterior and middle third of the pons. Below the tumor was a hæmorrhage about as big as a hazel-nut. The basal ganglia were pushed inward with the internal capsule, and the convolutions of the temporo-sphenoidal lobe outwards. The cortex was not at all involved. The white matter of these convolutions was somewhat affected, a small part of the tumor spreading into the island. No microscopical examination of the tumor was made, owing to the method employed in the hardening.

The article as published contains figures clearly showing the locality of the tumor, with the dimensions in various sections, also a lithograph of a letter written about three weeks before her death, unintelligible for the most part, though many individual words are distinct; "hoping you (they, the children, etc.) are all well" seems to be the substance of each sentence.

USE OF THE MOXA IN JAPAN.

As I rode behind the naked-backed jinriksha coolies I noticed along each side of the spine, from the head to the hips, white, irregular scars, about the size of a dime, indicating, as I supposed, some skin disease, to which they are very subject from their diet and exposure when young. These were the marks left by the moxa, a household remedy, probably invented in Japan, — a painful and powerful agent, well known in modern surgery. It is made of the pith of a reed (*Artemisia*), mixed with powdered charcoal, in a conical form. This is ignited, applied to the skin, and allowed to burn slowly until extinguished. The flesh is severely burned, with the resulting scar alluded to. As if this were not sufficient to expel the "winds and vapors," which they and the Chinese believe to be the cause of all diseases, this is combined with acupuncture, the needle passing through the moxa deeply into the tissues, and conveying the heat to the supposed seat of disease. As they employ this every spring as a preventive measure, it is rare to see a coolie without these scars. The accoucheur calls it to his aid, and is directed to burn three cones on the little toe of the right foot to accelerate the operation of nature. Even infants are thus tortured. A child about three years old, suffering from a wasting diarrhoea, who had thus been uselessly tormented, was brought to me; the many wraps having been removed, a simple water

dressing and mild opiate brought the little creature round all right in two days.

SAMUEL KNEERLAND, in *Science*.

IODOFORM FOR FISSURE OF THE ANUS.

DR. THOMAS HAY, in a communication to the *Medical and Surgical Reporter* (April 14, 1883), strongly recommends the local use of iodoform in fissure of the anus as a substitute for operation by the knife or forcible rupture of the sphincter muscle on the ground that it is equally efficacious with the operative method of treatment and at the same time milder and safer. He says: "It may be dusted, in *very fine* powder, upon and into the fissured parts, or applied in the form of ointment or suppository. The application of the simple powders, if properly prepared, three or four times a day, after each evacuation, and in the intervals, is often sufficient. In some cases, however, the undiluted powder — although thoroughly powdered — causes some pain. In such the iodoform may be mixed with powdered gum acacia, if a powder be preferred, or may be made into an ointment with vaseline, or suppository with the oil of theobroma. Balsam of Peru, carbolic acid, and oil of peppermint, will moderate the intensity of the iodoform odor; but this can hardly be requisite for application in this situation. The application of the remedy may be followed by a little smarting, but soon after its use the sensibility of the parts becomes benumbed, and even defecation may go on without consciousness, so far as concerns the development of pain during or after the process."

THE CHANGE OF MEDICAL OPINION IN REGARD TO THE CAUSE AND RECENT EXTENSION OF MALARIA.

A RECENT paper by Dr. Charles P. Russel, of New York, an authority on matters of hygiene and endemic diseases, is published in the *Medical Record* (August 18th), and is quite iconoclastic as regards the heretofore accepted ideas of this disease. After alluding to conflicting and unsatisfactory results of those who have thought to find a specific germ, a *bacillus malarie*, the writer frankly admits the complete failure to answer the question, What is the nature of the malarial cause? He adds: —

"In the August (1876) number of the *Popular Science Monthly* I published a brief account of the views then entertained almost universally as to the conditions from which malaria was regarded as springing, views in which, at that time, I concurred. Since then, however, I have been forced to materially modify my opinions on this subject. During a conversation some few years since with the late Dr. Hayes, the Arctic explorer, I was surprised to learn that malarial disease was not unknown in certain Arctic regions where the summer temperature almost never rose above 60° F., with an average for the warmest month of only about 45° F. Dr. Hayes himself had treated several cases of intermittent fever among the natives there. This disposed at once of the tradition that an average summer temperature of at least 59° F. is one of the essential factors in the causation of such disorders.

"Investigating the subject more thoroughly, I found many instances of the occurrence of malarial diseases in other places where vegetable decomposition was, to any great extent, impossible; and very many more in-

stances exist, as everybody knows, of spots where all the so-called conditions for the production of the malarial poison have always been present without such poison ever having manifested itself; and others still, in which, under similar circumstances, it has appeared only at rare intervals. The doubts thus excited were subsequently corroborated during a professional connection with several cases of mill dams alleged to have produced malaria, one of which I will allude to hereafter. Within a few years the assumption of the truth of the convictions upon this subject entertained by most physicians and hygienists has been the basis for a war upon mill-dams in the Middle and Eastern States. Assuming that the exposure periodically, by drawing off water, of lands contiguous to a stream, and, in fact, forming a portion of the river-bed when the mill-dam was full—such drawing off of a certain quantity of water laying bare a considerable area of submerged ground covered with vegetable growth—and that the action of the summer sun upon such vegetation must inevitably create malaria—there could be little question as to the deleterious influence of any mill-dam within certain latitudes upon the health of the neighboring community. But, unfortunately for this theory, there are thousands of mill-ponds within the specified regions of average summer temperature, presenting every prescribed condition for the creation of malaria, in whose vicinity chills and fever have always been unknown as much as yellow fever or the plague.

"In this connection it is proper to recall the fact that since the United States census of 1870 there has been particularly noticed an evident extension of the subtle miasmatic influence over regions previously exempt from it within the Middle and New England States. The additional effect of this disease-wave upon the naturally malarious site of New York City alone in this period was exhibited in the fact that from 1868 to 1872 the number of annual victims to these fevers increased three hundred and fifty per cent. It is well known that in places previously exempt from them miasmatic fevers occasionally appear and disappear without there having taken place any perceptible changes in the relations of the soil. Sometimes such fevers assume a widely epidemic or pandemic character, appearing to have broken loose from their native haunts in order to invade a great extent of territory. Thus, as Hertz and Proust inform us, the continent of Europe was almost entirely overspread by such pandemics in 1558, 1678, and 1679; from 1718 to 1722; from 1808 to 1811; from 1824 to 1827, and from 1845 to 1848. That the cause of malaria being thus disseminated is equally mysterious with that of most epidemics few will venture to deny."

Dr. Russel further cites localities that are essentially malarious, where, as far as known, malaria *has always existed*, and analogously always will. Manhattan Island together with its surroundings—Westchester County, Northern Long Island, and Eastern New Jersey—present the most familiar examples. While in some portions of these territories the existence of swamps and overflowed lands does appear to bear a positive relation to malarial affections, and their drainage does seem to be followed by a *diminution* of such diseases (*never, however, by their entire suppression*), in other instances the drainage of such places has been succeeded by a positive increase, rather than a subsidence of miasmatic troubles. We are, therefore, placed in a dilemma as regards the influence of drainage in

exterminating malaria. On the other hand, whether in miasmatic regions or elsewhere, he does not presume to deny that *thorough* drainage has a beneficial effect upon the *general* public health, when we consider the large category of diseases. But this result proves nothing as to the *cause* of malaria.

Again, there are elevated lands, even lofty mountains and extensive dry sandy plains, where none of the so-called conditions for malaria can be discovered in simultaneous operation, but where malaria is virtually constant. Such instances are very numerous, and stagger even the most ingenious of the swamp and germ theorists. To these gentlemen it may seem almost sacrilege that any intelligent reader and observer should become an iconoclast as to the idols which ages of study have built up for all future worship; nevertheless, so it is; and it is significant that some of the most distinguished scientific men have lately abjured the orthodox opinions in regard to the essential conditions for the production of malaria. In a *cause célèbre* tried at Pittsfield, Mass., in October, 1882, on account of an indictment brought against the owners of a mill-dam for creating malarial fevers, Dr. Paul A. Chadbourne, President of the Massachusetts Agricultural College, and ex-President of Williams College, testified that, as a professor in the Berkshire and Maine medical schools he had formerly lectured upon the nature of malaria. He then believed it to be of gaseous character, due to heat and decomposition of vegetable material, but he had since entirely abandoned that theory, and adhered to no opinion whatever, based upon sufficient facts to make it valuable, as to how malaria arises. Other eminent physicians and hygienists similarly confessed at this trial that after having formerly held the marsh and germ theories, they had recently given up both.

It is discouraging to be thus obliged to tear down what little we thought had been properly built up of a theory of disease, but if it is a faulty substructure the sooner it is out of the way the better, even if it leaves without a stone to stand upon.

CHARCOT ON SOME LOCAL NERVOUS MANIFESTATIONS.

THE *Birmingham Medical Review* for August publishes a short abstract of some of Professor Charcot's writings on certain local nervous affections whose manifestations belong rather to the department of surgery than of medicine. We reproduce one or two of these extracts. Regarding

LOCAL HYSTERICAL AFFECTIONS

Professor Charcot says that it is well known how a blow, or pressure, or other local cause, may determine the development of some manifestation of a diathetic disorder, such as rheumatism, gout, or syphilis, but it is not so well known that the local phenomena of hysteria manifest themselves in the same way under similar influences. This important fact was recognized by Sir B. Brodie, who has illustrated it by cases in his lectures on Local Nervous Affections. "In a case," says Brodie, "which is of no unfrequent occurrence, a young woman pricks her finger, or perhaps the finger is merely pinched. Soon afterwards she complains of pain extending from the finger upwards along the hand

and fore-arm. This probably is followed by a convulsion, contraction of the muscles of the arm, or by a continued contraction of the flexor muscles on the anterior part of the arm, so that the fore-arm is kept permanently bent; at least while the patient is awake, for the spasm is generally relaxed during sleep."

Professor Charcot relates a case in which spasmodic contraction of the wrist and hand followed an injury to the back of the hand from falling against a stool. There was complete anæsthesia of the whole hand, wrist, and lower half of the fore-arm. She was seen in consultation six weeks after the accident, and five days later the hand recovered spontaneously.

In another case a squeeze of the right fore-arm, causing some swelling and ecchymosis, was followed by severe pain, especially on attempts at motion, with rigidity of the hand, the two proximal phalanges of the four inner digits being flexed at an obtuse angle, and the distal phalanges extended. The contraction disappeared suddenly, and was followed by complete paralysis of motion and sensation affecting the whole upper extremity, and later on this extended to the lower extremity, though the paralysis of motion was less complete. There was complete right hemi-anæsthesia affecting common and special sensation, including vision and smell, and there was marked tenderness in the right ovarian region. From this time a number of hysterical symptoms manifested themselves, — dyspnoea, vomiting, convulsive cough, retention of urine, etc.

The usual symptoms of traumatic local hysteria are (1) exquisite cutaneous hyperæsthesia; (2) deeper pains in the course of nerve trunks or in the interior of joints; (3) contractions. These symptoms do not remain limited to the part affected, but may extend to the whole limb. They are liable to spontaneous exacerbations, during which there may be, in addition, swelling, redness, and elevation of temperature.

Such symptoms are usually the first indication of the hysterical diathesis, hitherto latent. When ovarian hysteria is fully developed, mechanical injuries no longer appear to produce these effects.

The diagnosis of such cases is always difficult, and the treatment should be, as far as possible, negative. Blisters and cauteries, galvanization and faradization, prolonged rest, and attempts at reduction, etc., are generally all productive of more harm than good.

THE SIGNIFICANCE OF DOUBLE SCIATICA.

In a recent clinical lecture Professor Charcot described the case of a woman, aged sixty-one, who had been operated on several times for scirrhus of the breast. She developed severe double sciatica, with pain in the region of both anterior crural nerves. The pains were exasperated by the erect position, so that walking became impossible. There was tenderness in the lumbar and sacral region of the spinal column, but there was no muscular atrophy, alteration of reflexes, or disturbance of the functions of the bladder or rectum. Professor Charcot insisted that double sciatica is always symptomatic, and the causes are (a) diabetes; (b) certain spinal diseases, for example, locomotor ataxy and meningo-myelitis; and (c) some alteration in the nerves themselves. There was no sugar in the urine, nor any evidence of those spinal affections; and in the absence of any sign of a tumor in the pelvis the readiest explanation was cancerous invasion of the vertebral column, causing pressure on the nerves. Secondary cancer of the spinal column was held by Ca-

zalis to be very common, especially after scirrhus of the breast, but it may be also met with in cancer of the stomach. In practice it is important to note that the presence of double sciatica in cancerous patients indicates metastasis, and contra-indicates operative interference. Conversely, severe neuralgic pains in patients at the age for cancer should suggest a careful examination of the breasts, the stomach, and the uterus. Such pseudo-neuralgic pains are the ordinary clinical signs of vertebral cancer, but a fungous mass may project from the spine, in which case the vertebrae will be infiltrated, and the consequences will be similar to those of Pott's disease.

SURGICAL EXPEDIENTS IN EMERGENCIES.

We reproduce from *The Polyclinic*, one of the ablest of the new candidates in the field of medical journalism, the following extracts from an ingenious and instructive paper by R. J. Levis, M. D. :—

It is in the experience of every surgeon to be occasionally obliged, in the absence of ordinary means and appliances, to devise resources available at the moment. Such occasions bring the practical character of the surgeon to the test, and on his readiness for the emergency may depend the relief of suffering or the averting of a fatal termination. His reputation, too, may, at such times, stand in the balance of good or ill report, to be turned happily in his favor or gravely against him.

The exigencies of active surgical practice have frequently obliged me to rely on hastily devised resources, and I trust that the record of some of them which I recall may possibly be of benefit to the profession and a relief to human suffering.

The necessity for *evacuating an over-distended bladder* is liable to become immediately urgent on occasions when a catheter is not quickly attainable. It is remarkable how often the condition is overlooked by practitioners until it becomes one of suffering and danger, demanding instant relief. The continued dribbling that often occurs from an almost bursting bladder may mislead or blind one to the grave danger. The absence of a catheter on one such pressing occasion led me to contrive a ready means of evacuating the urine. The recourse was to a piece of iron bell wire, bent double on itself, and the blunt doubled end passed readily through the urethral tract to the bladder. The distention of the urethra by the doubled wire allowed the urine to freely pass between the wires.

A *female catheter* may be extemporized from a short piece of rye straw, the end of which is to be closely wrapped for a short distance with thread; or the end of the straw may have its sharpness removed by dipping into melted sealing wax. The stem of the ordinary clay tobacco pipe is also efficient for the purpose. Such crude substitutes, when oiled, are readily introduced.

The *operation of venesection* would probably be more frequently resorted to when needed if a proper lancet, in perfect order, were at hand; but the critical time for relief of an actively congested or inflamed lung or brain is sometimes allowed to pass for want of a ready and certain method of opening a vein. I once, on a pressing occasion, bled a patient at the bend of the elbow, with perfect ease and precision, with but a blunt-pointed and dull pocket-knife, by resorting to a simple,

convenient expedient. Having put on the usual constricting bandage to distend the veins, I first transfixed the most prominent vein with a fine needle. Thus held securely, it was very easy, with even the dull knife, to cut a valvular incision into the vein, and the blood flowed freely.

For the arrest of nasal hæmorrhage I know of no device so good as one that may be readily extemporized with a strong piece of cord and some small pieces of sponge. The cord is tied securely to a piece of sponge, cut rounded, and just large enough to be forced backwards through the nostril. Then a number of similar pieces of sponge, with a hole through the centre of each, are threaded successively on the cord. The sponge on the end of the cord is then pushed, with a probe or dressing forceps, through the nostril, quite back to the faucial orifice; and the rest of the threaded pieces of sponge are slid back, one at a time, until the nares is tightly filled. When the patient becomes secure against a repetition of hæmorrhage the plugging is readily removed, one piece of sponge being withdrawn at a time, with the dressing forceps. The posterior nares may also be easily plugged by introducing either a slender gum bougie or a piece of thick catgut string, with a cord attached, through the nares, catching one end of it in the fauces with forceps, and drawing it forward through the mouth. To the cord which follows, a piece of sponge or pledget of lint is tied, to be drawn up into the posterior nares.

A method of making unirritating and painless pressure within the nares, in cases of obstinate epistaxis, is by a piece of the intestine of a chicken or other small animal, about twelve inches long, partially filled with either air or water. One end of the intestine is, while empty and collapsed, pushed backward through the nares; when thus lodged the air or water in the other end is forced, by compression with the hand from the pendulous portion, into the part lodged in the nares. Strong, equable compression can thus be made, rendering hæmorrhage impossible.

In a case of hæmorrhage from the intercostal artery, from homicidal stabbing, I arrested the flow immediately by making pressure within the pleural cavity, directly on the vessel, by introducing into the wound the handle of a door-key. The key was then turned transversely, so as to make direct pressure, and maintained in that position for some hours, until there was no more tendency to hæmorrhage. The same mechanical action might be effected by the similar use of the handle of an ordinary gimlet.

As a very efficient substitute for *Esmarch's elastic bandage*, I suggested, some years ago, in an article in the *Philadelphia Medical Times*, the use of a bandage made from ordinary flannel, cut bias, so as to increase its elasticity. Such an elastic bandage, from a material almost everywhere at hand, is, I know from experience, perfectly effective.

The hæmostatic action of hot water does not seem to be sufficiently known and appreciated among practitioners. It is so effective, and can be so readily applied, that it may well displace from practice all other hæmostatics. Water at a temperature not beyond tolerance of the immersion of the hand in it, which is a temperature of from 115° F. to 120° F., is ordinarily all that is necessary; but in some cases not amenable to treatment by the ligature, a temperature above 160° F., the coagulating point of albumen, may be necessary.

The absence of a tenaculum may be well replaced by a small fish-hook secured to a pen-holder.

For dislodging a foreign body in the œsophagus by forcing it downward, an ordinary carriage or riding whip, knotted far enough from the end to insure the proper degree of flexibility, may be an efficient expedient in an emergency.

Materials for splints for the temporary dressing of fractures can be at almost all times extemporized from the materials of wooden boxes and binders' boards. To dress fracture of the fore-arm and of the leg, in a case required to be removed to a distance from the scene of the accident, I once improvised an efficient dressing by breaking into strips some ordinary palm-leaf fans, which were at hand, and bound them on the limbs. I commend the material for its merits of being elastic and conformable to the shape of the limb. Good temporary dressings can also be made from common straw, cut to proper length and bound in layers on the limb.

For a readily made fixed dressing, a plan I have resorted to is with ordinary sand-paper as the material. The sand-paper is dipped into warm water, to soften the paper and glue, and it is then applied and retained with a bandage. The glue of the sand-paper soon gives rigidity; body and firmness are produced by the sand and paper. Strong fixed dressings, it should be remembered, can be readily prepared with the familiar domestic commodities of starch, or with the combination of eggs and flour.

In removing a patient with a fractured thigh or leg, the uninjured limb can be made to temporarily act as a splint and take care of the injured one, by simply bandaging the limbs together.

Many surgical instruments are made after traditionally complicated forms. Scalpels, bistouries, and needles should not be crooked. I know of no use for curved knives, and the occasions for the use of curved needles may be limited to a few plastic procedures in cavities. The ordinary surgical needle, with its absurd and inconvenient curve, I long ago discarded in favor of the more efficient, simple, and cheap glovers' needles. A good surgical needle can be readily made from an ordinary sewing needle, broken off above its point and ground to such an oblique point as is given to the hollow needle of the hypodermic syringe.

A common gimlet is an efficient instrument for opening the mastoid cells, in cases of abscess, when there is grave threatening of cerebral complication, demanding prompt action.

The patient use of a carpenter's rasp may safely substitute the trephine, in cases of fractured skull, by cutting away an angle or edge of bone at the point of fracture, and allowing an elevator, such as a small screw driver, to be inserted beneath a depressed fragment.

In regard to the traditional forms given to instruments, I have inquired of different instrument makers why the sharp, triangular point is made on the ordinary silver probe, but it remains unexplained. I have never seen any surgeon use this curious bayonet-point of a probe, and know of no possible use for it.

The facility with which rectal injection can be performed with large quantities of fluids, by hydrostatic pressure, renders not essential the use of a syringe, if a piece of India-rubber tubing long enough can be obtained. The lower bowels may also be distended, in cases of intussusception, by injecting water and car-

bonic acid gas, forced from the ordinary mineral water bottle or siphon, fitted to the rectal tube.

For antiseptic use many readily procured substances may well replace carbolic acid. None is so cheap and efficient as that most neglected preventer of putrefaction, sulphurous acid, made simply by exposing water to the fumes of burning sulphur in a close chamber. The antiseptic action of a saturated watery solution of turpentine has also the advantage of convenience of procurement and cheapness. For this purpose turpentine should be kept continually in water and exposed to warmth, and frequently agitated. Diluted alcohol

has merits as an antiseptic which have not received proper attention.

Recent investigations have proved that the bichloride of mercury is the most powerful of all germicides, and that it can be used effectively in unirritating dilutions of one part to two thousand or more of water. These readily obtainable substances prevent the decomposition of animal matters, and, without disputing over the germinal, chemical, or other theories of their action, all surgeons must admit that putrefaction is the most common factor in preventing the healing of wounds, and that it should be avoided.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 18, 1883.

Deaths reported 2979 (no report from New Orleans): under five years of age, 1442: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 1093, diarrhoeal diseases 735, consumption 368, lung diseases 163, diphtheria and croup 123, typhoid fever 72, malarial fevers 45, scarlet fever 41, whooping-cough 28, measles 24, cerebro-spinal meningitis 12, puerperal fever 10, erysipelas three. From malarial fevers, New York 23, Brooklyn nine, Philadelphia and St. Louis four each, Charleston two, Chicago, Baltimore, and Nashville one each. From scarlet fever, Chicago ten, New York, Boston, and Baltimore five each, St. Louis four, Philadelphia three, Cincinnati and District of Columbia two each, Brooklyn, Pittsburg, Buffalo, Cambridge, and Lynn one each. From whooping-cough, New York 11, Chicago four, Brooklyn three, Cincinnati, District of Columbia, and Pittsburg two each, Boston, St. Louis,

and Buffalo one each. From measles, New York 13, Brooklyn, Boston, Baltimore, and Pittsburg two each, New Haven, Lawrence, and Chelsea one each. From cerebro-spinal meningitis, New York, Chicago, Buffalo, and Malden two each, Milwaukee, Fall River, Haverhill, and Westborough one each. From puerperal fever, Boston three, Chicago and St. Louis two each, Philadelphia, Brooklyn, and Nashville one each. From erysipelas, New York two, Brooklyn one.

Two cases of small-pox were reported, in St. Louis; typhoid fever 23, diphtheria 17, scarlet fever 17, and measles two in Boston; scarlet fever eight, diphtheria seven in Milwaukee.

In 42 cities and towns of Massachusetts, with an estimated population of 1,196,174 (estimated population of the State 1,922,530), the total death-rate for the week was 22.86 against 25.72 and 26.53 for the previous two weeks.

In the 28 greater towns of England and Wales, with an esti-

mated population of 8,620,975, for the week ending August 4th the death-rate was 20. Deaths reported 3296: diarrhoea 305, acute diseases of the respiratory organs (London) 168, measles 139, scarlet fever 95, whooping-cough 49, fever 47, diphtheria 22, small-pox (London, Birmingham, Sunderland and Newcastle one each) four. The death-rates ranged from 9.7 in Plymouth to 33.2 in Newcastle-on-Tyne, Birkenhead 11.2; Halifax 15.2; Norwich 17.5; Leicester 18.1; Bradford 19.1; London 19.3; Birmingham 20.2; Sheffield 20.3; Leeds 22.6; Manchester 23.4; Liverpool 28. In Edinburgh 20.3; Glasgow 24.9; Dublin 17.2.

For the week ending July 28th, in 172 German cities and towns, with an estimated population of 8,754,694, the death-rate was 28.8. Deaths reported 4857; under five years of age, 2935; diarrhoeal diseases 510, consumption 505, lung diseases 312, diphtheria and croup 139, measles and röteln 82, scarlet

fever 77, typhoid fever 54, whooping-cough 50, puerperal fever 18, small-pox (Heilbronn one) one, typhus fever (Königsberg one) one. The death-rates ranged from 13.0 in Erfurt to 41.6 in Berlin; Königsberg 31.8; Breslau 33.6; Munich 37.7; Dresden 29; Leipzig 28.5; Hamburg 20.5; Cologne 28.7; Frankfurt a. M. 16.7; Straasburg 25.8.

For the week ending August 4th, in the Swiss towns, there were 27 deaths from diarrhoeal diseases, consumption 21, lung diseases seven, diphtheria and croup five, measles three, whooping-cough two, puerperal fever two, typhoid fever one. The death-rates were at Geneva 11.3, Zurich 16, Basle 30.5, Berne 20.13.

The meteorological record for the week ending August 18th in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM AUGUST 17, 1883, TO AUGUST 24, 1883.

CLEMENTS, BENNETT A., major and surgeon. Relieved from duty with the Army Medical Examining Board, New York City, N. Y. Paragraph 11, S. O. 193, A. G. O., August 22, 1883.

MIDDLETON, J. V. D., major and surgeon. Relieved from duty at Fort Hays, Kansas, and assigned to duty at Fort Leavenworth, Kansas. Paragraph 2, S. O. 169, Department of the Missouri, August 18, 1883.

WILLIAMS, JOHN W., major and surgeon. Granted leave of absence for one month on surgeon's certificate of disability. Paragraph 1, S. O. 109, Department of the Columbia, August 8, 1883.

BARTHOLOMEW, JOHN H., captain and assistant surgeon. Assigned to temporary duty at Vancouver Barracks, W. T. Paragraph 2, S. O. 109, Department of the Columbia, August 8, 1883.

FINLEY, J. A., captain and assistant surgeon. Relieved from duty at Fort Concho, Texas, and assigned to duty at Fort Stockton, Texas, as post surgeon. Paragraph 1, S. O. 101, Department of Texas, August 16, 1883.

KIMBALL, JAMES P., captain and assistant surgeon. Relieved from duty in Department of the Platte, and to proceed to New York City, and report in person to the President of the Army Medical Examining Board for duty as a member of that board vice Surgeon Clements, relieved. Paragraph 11, S. O. 193, A. G. O., August 22, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING WEEK ENDING AUGUST 25, 1883.

AUSTIN, A. A., assistant surgeon, ordered to Naval Hospital, New York.

CRAIG, T. C., assistant surgeon, detached from the Naval Hospital, New York, and ordered to the U. S. S. Minnesota.

CRAWFORD, M. H., passed assistant surgeon, detached from the U. S. S. Pinta, and placed on sick leave.

WILLSON, W. G. G., passed assistant surgeon, detached from the Minnesota, and ordered to the Pinta.

WHITE, CHARLES H., surgeon, ordered to the Museum of Hygiene, Washington, D. C.

BRYAN, J. H., passed assistant surgeon, detached from the Museum of Hygiene, and ordered to the Miantonomoh.

GUITERAS, D. M., passed assistant surgeon, ordered to the Navy Yard, Pensacola, Fla.

BOOKS AND PAMPHLETS RECEIVED.—Transactions of the South Carolina Medical Association. Thirty-Third Annual Session. Held in Yorkville, S. C., April 25 and 26, 1883.

Report of Proceedings of the Illinois State Board of Health. Quarterly Meeting, Springfield, June 29, 1883.

Answers to Practical Questions on the Subject of Diphtheria. Reprinted from Therapeutic Gazette.

The Sanitary Engineer. Bound Volume No. VII. December, 1882, to May, 1883.

Fourth Annual Announcement and Catalogue of the Northwestern Medical College of St. Joseph, Missouri. Session 1883-1884.

On Nasal Cough and the Existence of a Sensitive Reflex Area in the Nose. By John N. Mackenzie, M. D., of Baltimore, Md., Surgeon to the Baltimore Eye, Ear, and Throat Charity Hospital. (Reprint.) 1883.

A New School Physiology. By Richard J. Dunglison, A. M., M. D., Author of The Practitioner's Reference Book, etc. Illustrated with 117 Engravings. Philadelphia: Porter & Coates.

Excision of the Knee-Joint. With Report of 28 Cases. Illustrated by 13 Photo-Lithographs and Wood Engravings. By George Edgeworth Fenwick, M. D., C. M., Professor of Surgery, McGill University, etc. Montreal: Dawson Bros. 1883.

Closing Exercises of the Practitioners' Course of Lectures. Delivered in the Spring of 1883 in the Hahnemann Medical College and Hospital of Chicago, Ill.

Transactions of the Medical Society of the State of West Virginia. Sixteenth Annual Session. Held in Grafton, May 16 and 17, 1883. Wheeling. 1883.

Eighth Report of the Salem Hospital. Salem. 1883.

RECENT INVESTIGATIONS INTO THE PATHOLOGY OF SO-CALLED CONCUSSION OF THE SPINE,¹

WITH CASES ILLUSTRATING THE IMPORTANCE OF SEEKING FOR EVIDENCES OF TYPICAL HYSTERIA IN THE CHRONIC AS WELL AS IN THE ACUTE STAGES OF THE DISEASE.

BY JAMES J. PUTNAM, M. D.

THERE are few kinds of disease with regard to which the interpretation of evidence is of so much importance as compared with the simple accumulation of evidence as in the case of the so-called concussion of the spine.

A man is bruised and shaken up by a severe fall or the jar of a railway collision. When we see him his limbs may appear to be more or less completely paralyzed, or he complains of extreme pain which is aggravated by the slightest motion, while his expression of distress proclaims him to be a very sick man, and enlists our anxiety and our sympathy in his behalf. By what signs can we discover whether he is really suffering from a serious, if not incurable, affection of the nervous centres, to which many of the symptoms point, or whether his case is one of those which are susceptible of considerable and even rapid improvement, especially after the conclusion of legal complications?² This question is often hard enough to answer, and the difficulty is still greater if the patient has recovered from the immediate effects of the injury so that we have only his own word to vouch for the reality of his complaints.

Fortunately, it seems to be becoming more and more apparent that the real difficulty in the way of diagnosis lies not so much in the obscurity of these cases themselves as in the fact that the greater part of them belong to a type of disease which has not until of late years been intimately studied. The profession has not even yet generally agreed upon such a classification of symptoms as would enable us to separate the essential from the non-essential, the serious from the trivial, and the appearance of suffering presented by the patients is sometimes so impressive that the temptation is too strong to be resisted to judge each case on what we conceive at the moment to be its true merits instead of trying to refer it to some relatively familiar class of diseases, and reasoning about it as from the greater to the less. On the other hand, in the more chronic cases the apparent absence of tangible signs of disease, combined with a suspicion that the sickness is being feigned for damages' sake, has undoubtedly often led to an underestimate of the patient's real disability. For this state of affairs the retention in medicine of the term "spinal concussion" is certainly in part responsible in that it satisfies in a measure the imagination, and excuses the clinical observer from seeking for a more rational explanation of the symptoms which are brought to his notice. The expression is no doubt convenient, and has served a useful turn, but it is

¹ Read before the Boston Society for Medical Improvement, May, 1883.

² Mr. Page, in his recent *Injuries to the Spine*, to be referred to later, dwells particularly on the important point that a rapid improvement after the settlement of legal claims is by no means a proof that the patient's symptoms were imaginary or assumed, an inference which is often unjustly drawn.

worth while to recognize occasionally that as a diagnosis it has no real meaning. In spite of all the attention which has been given to the subject we know of no pathological state of the spinal cord to which the name of concussion could properly be applied, and it is evident that some at least of the symptoms usually designated by it can be grouped under other headings.

The interesting paper read before this Society by Dr. Hodges in January, 1881, was a move toward the adoption of a more rational classification, and our lines can now be pushed out a little further. Whereas Erichsen uses the expression "spinal concussion" almost indiscriminately for the cases of organic and those of functional character. Dr. Hodges thinks that the former can and should be separated from the latter, and designated by their proper pathological name, as myelitis, meningitis, etc., which at once invests them with a clinical history and prognosis on which we can reckon.

Still more recent investigations to which I shall refer, limit very materially the part played by organic disease, showing that it is of the very rarest occurrence in cases of injury from simple jar. At the same time it can, I think, be made probable that the group of functional cases is capable of further classification, and that some of them at least can be proved beyond the possibility of deception to be examples of that important neurosis which is called hysteria, a term which, thanks to the labors of Charcot and his pupils, has vastly outgrown its old and vague meaning, and is constantly acquiring a more precise and practical significance. The term "concussion of the spine" is even more conspicuously a misnomer from the fact that it calls away the attention from the more recent investigations into the real pathology of the affection at stake.

Thus it is probable that in the production of many of the hysteroid symptoms it is a disturbance of cerebral rather than of spinal functions which is at fault, and it has been plausibly suggested that both spinal cord and brain suffer for the most part only secondarily, as a result of changes in blood pressure, which in their turn are due to the concussion of the great abdominal organs with their nerves and ganglia.

Within the past year an exceedingly valuable book has appeared, by Mr. Herbert Page, surgeon to the London and Northwest Railway, in which a thorough and critical analysis is made of the literature of the subject, and 250 new cases are reported in tabular form out of a much larger number which the author has observed in support of the conclusions which he draws.

The opinion of prime importance at which Mr. Page arrives is that it is an event so rare as to constitute a marked exception to the rule for the spinal cord to receive any injury in concussion accidents, however severe, so long as the bony canal which protects it, as no other organ in the body is protected, remains intact.

Where such injury does occur, as has been attested by unequivocal clinical signs, the history of the case is not that of simple concussion, and the termination is almost always fatal. Conversely, he would maintain that cases of the kind usually considered typical of concussion do not, except in the rarest cases, show unequivocal signs of spinal injury or disease. Scarcely a single autopsy proving such an injury is in fact on record.

I gather from carefully reading the book that in the opinion of the author a classification of the following

sort might be made of the cases of organic injury of the cord:—

(1.) Those directly or indirectly due to fracture or displacement of vertebræ.

(2.) A very few cases where the cord has sustained manifest and usually fatal injury without apparent lesion of the vertebral column.

Such cases as these are not observed among those originating in the jar of a railway collision, but are due to such accidents as a fall from a great height or a severe blow, localized at some one point of the back, or to a sudden or severe bending of the body. In all of them the symptoms of spinal-cord disease are unequivocal, and make their appearance immediately after the accident. The writer is inclined to believe that in the majority of the cases in which unequivocal symptoms show themselves which pass entirely away after a moderate time, too short for a myelitis to run its course, the cord is probably suffering from the pressure of a hæmorrhage which is soon absorbed. Besides these cases of undoubted injury, a few have been observed in which death followed after a short time and in which no lesion could be found in the spinal cord, as in the instance so often referred to as observed by Leyden, and one reported by Bastian in which death occurred after a lapse of five months. In this case no changes were discovered with the naked eye, but the microscope revealed pretty extensive and diffused lesions which Bastian considers to be the results of material interference with the circulation in the small vessels, due, he believes, to pressure upon them from blood effused into their sheaths through rents in their walls.

It is also probable that chronic degenerative affections of the cord, such as locomotor ataxia, or other forms of sclerosis, are occasionally of traumatic origin, and Dr. R. T. Edes has reported several instances of this sort. Perhaps Mr. Page underrates the frequency with which these cases occur, even as a result of railway accidents; but certainly they are comparatively rare.¹

There remains for consideration the vast mass of cases of the kind seen after ordinary concussion accidents, presenting symptoms which sometimes lead competent observers to diagnose chronic myelitis or meningitis.

The special service which Mr. Page has rendered lies in subjecting this diagnosis to a searching examination, in the course of which he shows (1) that a favorable termination of these cases is far more common than our knowledge of the serious diseases referred to would lead us to expect; and (2) that the affections to which concussion accidents unquestionably do give rise, such as reflex functional disorders, sprains of muscles and ligaments and the like, are capable of simulating to a remarkable degree real organic diseases of the cord.

This latter fact has, of course, been insisted on by various writers, but not before, so far as I know, supported by such a weight of evidence. And this is, after all, the important point; for, although every one is aware that in going to a case of this kind, he is liable to meet with symptoms, really not serious, which may closely simulate disease of the spinal cord or

membranes, he is usually not aware *how great* this liability to error is; and no one can fail to be impressed with Mr. Page's opinion that real injury of the spinal cord or its membranes, in railroad accidents at least, is almost an unknown occurrence.

In investigating for the first time, therefore, a case of concussion, presenting acute symptoms, no matter how apparently grave, the proper course would seem to be to suspect and search carefully for the presence of functional symptoms which may be grouped under the term hysteria, and to consider whether, if present, they may not give the true key to the patient's state. Such symptoms, in *acute cases*, would be widespread anæsthesia, not limited to the paralyzed limbs; the absence of atrophic changes or loss of electrical irritability in paralyzed muscles; persistence or distortion of the so-called tendon-reflexes; absence of disturbances of micturition, or retention of urine out of proportion to the other symptoms; exaggerated tenderness of the spinal region, and complaint of pain there excited by a trifling jar, or handling of the limb; a very late onset of the symptoms after the injury; a highly emotional mental state or, on the contrary, excessive apathy. A striking case, illustrating some of these points, was recently seen by me at the Massachusetts General Hospital in the service of Dr. John Homans, who kindly allows me to make use of it.

The patient was a young Irish girl, seventeen years of age, and only recently arrived in this country, who was brought to the Massachusetts General Hospital on June 25, 1882, having fallen down a flight of cellar stairs, striking upon her back and right hip.

On her arrival at the hospital she appeared to be paraplegic, both as regards sensation and motion. There was tenderness over the lumbar region; no dislocation or fracture; a slight bruise over right trochanter.

The patient was able to pass her urine. Her general condition was excited and hysterical.

Two days later she could move her feet a little, and on the third day could turn in bed, and the condition of the sensibility had somewhat improved, the tenderness over the spine continuing, however, without change.

I saw her for the first time at the request of Dr. Homans, about three weeks after the accident. She was then lying on her back, as she had been throughout, and while still, looked comfortable enough. She could draw up the legs, and in fact make every motion, although but feebly, but was very unwilling to be handled or moved, complaining of severe pain in the back. This was so severe that meningeal irritation was thought of, though the diagnosis of hysterical paralysis was finally made. The sensibility of the legs was impaired but by no means lost. The skin was dry and exfoliating.

A few days later the attempt was made to get her on her feet, although she cried out with pain. At first she could scarcely support her weight in the least, but in the course of two or three weeks she could hobble a short distance on crutches, the improvement being due largely to the perseverance of Dr. Howard Lombard, then assistant in the hospital.

On the 9th of August, nearly two months after the accident, she was attacked with what seemed to be acute gastric catarrh, vomiting all food. She was confined to bed, and suddenly, within a day or two, became absolutely paraplegic, and her lower extremities lost all sensibility to every kind of excitation.

¹ During the discussion which followed the reading of this paper before the Society for Medical Improvement, the criticism was made by Dr. Webber and others that Mr. Page attaches too much weight to the absence of post-mortem proof as indicating the rarity of organic disease of "concussion" or "contusion," and that it is not difficult to suggest other possible causes for the fact.

A day later the right arm became absolutely paralyzed and insensitive like the legs. She was seen by several physicians, and though the opinion that this, too, might be a hysterical manifestation was entertained, her condition was such as to excite the most serious anxiety.

For several days she lay like a log in the bed, unable to retain food or to pass her urine, both legs and the right arm extended and motionless, the muscles flabby and sodden, the skin absolutely insensitive, the expression of the face heavy and apathetic, scarcely any response to questions to be got out of her. At this time I went into the country for a few weeks, but learned from the assistant, then Mr. Holden, on my return, that after a few days the patient had become brighter, and the suspicion of hysteria becoming stronger, he had, by coaxing and urging, induced her to make a slight movement of the arm.

From this time improvement progressed steadily, and she was helping about the ward in a few weeks, and a few months later came to see me in the out-patient department, strong and rosy and completely restored to health except for the sensibility of the skin, which remained, and perhaps will always remain deficient.

Still more important, from the medico-legal point of view, is the fact that even in chronic cases where the patient presents no symptoms that might not more or less readily be feigned, it is sometimes possible by careful searching to discover signs of the so-called hysterical state, which, although not strictly objective, have almost the same value as if they were so as evidence against malingering.

So far as I know, this fact has not previously been noticed, certainly it has not found its way into the literature of the "railway spine." I have recently seen two striking instances of the kind, and I publish them for the sake of calling attention to the matter on the chance that such cases may prove to be commoner than might be supposed.

It is well known that typical chronic hysteria in women is apt to reveal itself by a loss of sensibility, either confined to one side of the body, or much more markedly developed there, and often involving in a peculiar manner the organs of special sense. Thus the field of vision is concentrically and often extremely narrowed, the color sense greatly impaired, the hearing diminished, and diminished especially for high tones, and much more for conduction through the bones of the head, as has only recently been shown by Dr. G. L. Walton, than for conduction through the air in the ordinary manner, and all this in patients who may be walking about, and are to outward appearance in blooming health. In men, on the other hand, as were my two patients, this condition of hemianæsthesia is very rare.

The first case¹ is that of a fireman, a large, powerful, and robust man, who, about six months before he presented himself at the Massachusetts General Hospital, was riding on the top of his engine, when it was over-set, and he was thrown violently to the ground. He was somewhat stunned, and severely bruised over his right side, and it was some weeks before he could do much with his right arm and leg, though they appear never to have been really paralyzed.

¹ This case has been reported at length by Dr. G. L. Walton in the *Archives of Medicine*, New York, for July, 1883, with interesting observations on the effect of the magnet. It is therefore given here only in brief outline.

When he presented himself at the out-patient department of the hospital all signs of outward injury had passed away. His gait was awkward and guarded on account of the painful stiffness of the right leg, and the movements of the arm were painfully restricted for the same reason. He complained of prostration, wakefulness, and impairment of memory, and was evidently inclined to emotional outbreaks. Besides these and similar symptoms the following signs were discovered by Dr. Walton and myself, and they seemed to us of special interest from the fact that the patient was unaware of them, and that he was making no legal claim for damages: The whole right side, and to some extent the left, was found to be anæsthetic, so that a pin could be thrust through a thick fold of the skin without exciting pain. This cutaneous anæsthesia involved the external meatus, and also the special senses of sight and hearing, the latter especially for bone-conduction.

The effect of a blow on the patella tendon was very peculiar. Instead of exciting simple extension of the leg at the knee the leg was either drawn in by a quick movement of flexion,² or there was a quick to and fro movement, and at the same time the right hand gave a quick jerk, and then continued to oscillate for several seconds.

The painful stiffness of the arm and leg was considered to be due to adhesions in or about the muscles covering the joint,³ and this diagnosis was borne out by the effects of treatment. Dr. Walton's subsequent investigations also established beyond a doubt the general diagnosis of hysteria.

The second case is that of a man of about fifty years of age who recently sued a railroad company for damages received under the following circumstances: He had been sent to do some work within a car house on a siding, of which the door, weighing three hundred or four hundred pounds, was off its hinges, and was kept in place by a strip of wood nailed across. The plaintiff, who claims to have been ignorant of the condition of the hinges, tore off the strip of wood, and tried to pry the door open, when it fell over on him and crushed him to the ground. He was seen within a day or two by a careful physician, who testified to the finding of severe bruises and extensive ecchymoses all over the right shoulder and side, and that the patient seemed to have been affected in his general condition by the accident.

At the time of the suit (two years later) the patient made the usual complaints of sleeplessness, loss of flesh, strength, and energy, and of great pain about the shoulder, occurring both spontaneously and on motion, in consequence of which he was obliged to carry the arm constantly in a sling, and in fact inspection showed just about the amount of wasting of the scapular muscles as might be expected to follow prolonged rest, but no loss of electrical irritability nor other sign of neuritis. There were also some spots of exaggerated tenderness to which I did not attach much importance. What seemed to me of by far the most significance was the discovery of well-marked analgesia of the entire right side, including leg and face, though nowhere so pronounced as in the region of the right arm and shoulder. Here a pin could be passed through

² For similar distortions of the reflexes in hysteria see Dr. Mitchell's *Nervous Diseases*, especially of Women.

³ Compare A Painful Form of Peri-Arthritis of the Shoulder, by James J. Putnam, M. D., *Boston Medical and Surgical Journal*, 1883.

a fold of skin from side to side without provoking the least sign of pain. This condition had never been referred to by the patient, and as far as is known he had never been aware of it. The sensibility was further tested by the use of a faradic wire brush with a strong current, which, as is known, is an excessively painful application, but even when this was used suddenly, without warning, over the sensitive skin of the scapular region the patient did not wince. The field of vision was not diminished in this case, and there was no impairment of the color sense nor of hearing.

In view of this hemianæsthesia, which I think the patient could not have feigned, together with the pretty clear indication that the arm had been carried in a sling not in the court room alone, for effect, but pretty continuously for a long time, I think the patient's statement of his general condition must be admitted to gain in credibility.

Of course it is not to be concluded that because a patient is shown to have hemianæsthesia he is therefore, practically speaking, a sick or disabled man. On the contrary this is a symptom of hysteria which often outlasts all the rest, and many women carry it through life even if in relatively good working health. What it does show, however, if occurring in a male patient, is that his nervous system has in all probability been subjected at some past time to some considerable perturbing influence, and its presence or absence might prove a welcome aid to diagnosis in other obscure cases as it did in this.

(1.) A CASE OF OSTEO-MALACIA WITH AUTOPSY. (2.) A CASE OF SUPPRESSION OF URINE, WITH AUTOPSY.¹

I.

I was called to Mrs. H. late in the evening of March 16, 1872, who had fallen and hurt herself; saw her within half an hour, and found that she had a fracture of the left thigh at lower third.

Her story was that while going from one room to another on her way to bed, as she stepped across the threshold she felt a snap and fell with the result spoken of.

The limb was treated with coaptation splints, extension by weight and pulley, and raising the foot of the bed.

She was a thin, spare, hard-working woman, with a marked dirty, sallow, earthy look, and although in comfortable circumstances had lived very frugally, — too sparingly, as far as I could learn. She was fifty-five years old, married, had had six children. Born in New York city. Her mother died at thirty-seven of consumption, her father at sixty-four.

On inquiry in regard to her general health, I found that she had been under the care of an irregular and very ignorant practitioner for some time, and treated for "rheumatism," and for six weeks before her fall had not been able to walk without crutches.

She bore her confinement to the bed well, had less "rheumatism," as she called it, in her thigh, and in six weeks had good union, extension taken off, and some attempts made to use the leg and flex the knee — much against her wishes. She complained a good deal of pain in thigh, and soon it was found that union had

given way and that there was decided shortening. Splints were reapplied and extension, but with less weight, so that after confinement for six or eight weeks more there was good union.

At the end of three months or more she could sit up, and with the assistance of her husband and children move about the rooms. She never, however, bore her weight on her left foot; always used crutches and had no motion of the knee.

She was in this state till September, six months after her fall, when I was again sent for and found great retraction of the leg, at least six inches shortening. She told me that for some time there had been severe pain in thigh, and she feared that possibly there might be, as a result, another fracture, which I found was the fact.

Again she went to bed, and for the first time I suspected the true state of things. She never left her bed after this.

The next prominent symptom was pain in the lower part of the bowels, and on examination a fibrous tumor, as large as the head of a child, was found in the right iliac region.

During the following winter the left leg became painful; soon there was found to be marked eversion and of course fracture of both bones of the leg just below the knee. The next year the right thigh and leg became similarly affected, though I cannot remember in which order it came on.

From this time the progress of the disease was more rapid; the right forearm at its middle, and then the right humerus, softened and gave way. The left arm never completely separated, though it was very much bent.

The ribs and sternum softened gradually, so that there was a good deal of dyspnoea from atmospheric pressure.

For nearly a year she was utterly helpless, could only move her head from side to side, and had a little motion to the fingers of her left hand.

She died nearly four years after the first appearance of the disease.

Pain, especially in the long bones, was a marked symptom before they softened and separated, and she always spoke of them as breaking when she felt these attacks coming on.

The phalanges of the fingers lengthened visibly before separating, and the third phalanx of left hand became longer than the second.

In the urine I never found any trace of earthy matter that is so often spoken of as being present. Its general appearance was normal.

Post mortem by Dr. E. G. Cutler, twelve hours after death.

No rigor mortis. Distortion of the legs and arms, shortening of the same, and of the hands, was marked. The bones of the head seemed to the external touch not softened. The clavicles were entire and of normal shape and size; in removing the sternum the knife easily cut through both near the junction with the sternum; they were seen to be composed of a thin layer of bony tissue inclosing a medullary substance of a dark red color, very like russia leather in tint. The sternum was very friable and could be cut with greatest ease in all directions with a knife. It was also hollowed out completely, and filled with the same kind of medullary tissue, which, however, in spots was of lighter color. The cartilages in the neighborhood of the sternum and

¹ Two Cases reported by Dr. L. R. Stone, to the Boston Society for Medical Observation, May 21, 1883.

ribs were also hollowed out to a certain extent, and the spaces thus left in like manner filled with the medullary substance.

The entire length of the body when straightened out on a board was forty-six inches from the crown to the soles of the feet (she was about medium height). The right arm from the acromion process to the tip of the ring finger, the longest finger in each hand, was fifteen inches long. The left arm from the acromion process to the tip of the ring finger was twenty-four inches long. The humerus, radius, and ulna of the right arm was scarcely to be recognized except at the shoulder, elbow, and wrist-joints, which were made out with tolerable clearness. The bones of the metacarpus were much shortened, as were also the phalanges. The humerus of the left arm was also scarcely recognizable to the touch, though the shoulder-joint and elbow were tolerably good. The fore-arm was completely flexed on the arm, and held by firm adhesions in this position. The radius scarcely perceptible except at the wrist-joint. The ulna softened, its normal length retained, and bent to a right angle nearly where it had rested on the chest. Both the extensor and flexor muscles could be felt on bending the fingers; they were, however, in the highest state of atrophy.

Right leg from the anterior superior spinous process of the ilium to the patella was twelve inches; from the same to the sole of foot eleven inches (twenty-three inches entire length).

Left leg from anterior superior spinous process of ilium to patella thirteen inches; thence to sole of foot twelve and one half inches (twenty-five and one half inches entire length).

The ribs on the right side were fractured in four distinct lines of fracture between the cartilages and just in front of the angles. On the left side there were five distinct lines of fracture. The diaphragm on the right side had the highest point of its arch under the third rib, on the left at the fourth intercostal space.

Nothing remarkable about the heart.

Hypostatic congestion in the posterior part of the lower lobes of both lungs. No calcareous deposits were found, though sections were made in all directions. The lungs contracted normally on section.

Liver hyperæmic, dark (not icteric), of normal size.

Spleen not remarkable.

Calcareous granules of very small size lying loose in the pelvis of each kidney. Under microscope seen to have an appearance not unlike starch granules or corpora amylacea, with a centre composed of cells. By treating same with a drop of very strong acid, microscopic bubbles of gas were evolved, and the granules disappeared, leaving only epithelial cells as a nucleus (carbonate of lime).

Intestines, stomach, and pancreas not remarkable.

Ovaries in usual condition of atrophy with cicatrices.

Fundus of the uterus occupied by a fibrous tumor, size of a child's head, which had undergone the serous infiltration. The tumor was interstitial, and projected from the very top. The cavity of the uterus was two inches in length, the cervix one and one half inch. It could not be determined if the os internum was impervious. The conjugate diameter of the pelvis was rather less than two and one half inches. Distance between the two anterior superior spinous processes was eight and one half inches. Sacrum was much curved. The pelvis was only narrowed antero-poste-

riorly as far as could be determined. The ischia were only slightly curved in. The promontory of the sacrum was hard to determine.

The vertebral column, the body being pulled straight, curved strongly towards the left, with the concavity on the right. The usual curve behind at the lumbar vertebrae was almost wholly effaced.

A section was made into the right thigh. The muscle was found reduced to mere lines of connective tissue directly underneath the skin, and immediately following was the remains of the femur, consisting of a thin plate, one half of a line in thickness, filled with a medullary substance which coarsely resembled in appearance a fresh blood-clot.

The microscopic examination of the medullary substance showed it to be composed of blood corpuscles and vessels, fat cells, and free fat granule corpuscles. Muscular tissue fatty infiltration; fat in the sarcolemma; many blood-vessels outside same.

The bone was seen to be deprived of the lime portion, and the Haversian system much enlarged.

She had false teeth.

II.

W. S. G., school-boy, aged seventeen years, six months, American parentage. Pale and delicate looking. I was called to see him on Wednesday, the 18th of October, 1882. He had not been well for a day or two, but on this day a slight eruption, with some swelling, appeared on face and forehead. Some heat and itching with it, but no fever, nor thirst, nor vomiting. The eruption had a slightly papular feel. As he had been tramping through the woods a few days before, shooting, I thought possibly he might have poisoned himself by ivy. Alkaline wash to face, with vaseline, light food, and in-doors was ordered, and the family to call me again if any new symptoms appeared, or he was not relieved in a few days.

He stayed in the house on Thursday, the 19th, but the next day, as the eruption had disappeared and he felt so well, he went to school for part of the day. He was considerably tired and stayed at home, about the house, however, and I was called to see him again Tuesday, October 24th.

I found him in bed, coughing slightly (he had been subject to asthma); temperature 103° F.; pulse 115; respiration 25. Vomiting occasionally. Slight diarrhoea. Urine high colored (I did not see it). Slept badly. No delirium. Felt weak. No nose bleed, no tinnitus aurium. No physical signs in chest.

Wednesday, October 25th. Temperature 102.02° F.; pulse 110; respiration 25. Vomiting continued, with slight diarrhoea. Slept rather better. Cough still troublesome, but nothing in lungs.

Thursday, October 26th. Less fever. Temperature 101° F.; pulse 100. Vomiting occasionally. Thirsty. Slept fairly well. Some, but less cough, with occasional rale at lower left back.

Friday, October 27th. About the same. Cough, and some pain in side. Vomiting occasionally; constant nausea. Pulse and temperature less than yesterday. Condition of lungs as day before. To-day urine was spoken of as peculiar — very dark, like blood.

Saturday, October 28th. Had a poor night. More pain in both sides, extending to back. Temperature 100° F., and pulse, as day before, 100. Vomited more. Uneasy and restless. Lies on back, with knees drawn up, though no tenderness at epigastrium or in either

hypochondrium. Bowels moved. Passed about three ounces of urine this morning, very dark, with blood in it. I saw him again in evening; had passed no urine. Milk and lime water, with also carbonic-acid water, ordered to relieve vomiting. Bromide of potassium, with chloral, to procure sleep.

Sunday, October 29th. Temperature 100° F.; pulse 90; respiration 24. Had a bad night. Vomited more frequently. Coughed more. Little more pain in sides. This morning found diminished resonance at base of left lung posteriorly, with increased voice and bronchial respiration, and bloody expectoration, which increased through the day, quite thin and very profuse. No appetite. Restless. No urine at all passed through the night nor this morning, though he made repeated attempts. No fullness over bladder. Diuretics ordered, and water freely.

Monday, October 30th. Temperature 99° F.; pulse 88; respiration 24. Physical signs not increased. Restless night. Vomiting persists. Has passed no urine; no desire to urinate. No pain. Expectoration very profuse.

Tuesday, October 31st. Same general report as of the day before. No urine; no desire to make water. No fullness over bladder.

Wednesday, November 1st. Temperature 98.5° F.; pulse 80; respiration 20. Vomiting more frequently and larger amounts. Coughs more; less expectoration. Has not passed urine now since Saturday morning, and no inclination to make water. By catheter I drew off about ten ounces, very high color, with some albumen. To-day a marked urinous odor to breath could be detected, but none to the skin or vomitus. Quite bright. Only complains of the vomiting. His voice somewhat hoarse or husky. Hands felt numb, very moist, and sticky.

Thursday, November 2d. Slept fairly well, though, in his words, he "felt all broke up." Temperature 98.5° F.; pulse 80; respiration 22. No urine; not a drop since catheterization day before.

To-day I tried sweating, but without any relief or success. Dr. Morrill Wyman saw him in consultation.

Friday, November 23d. Bad night. Coughed some. No fever, not much pain. Vomited more. Several loose discharges from enema of day before. Weaker. No urine; no desire to urinate; no indication of any in bladder. As the family did not feel satisfied with Dr. Wyman's grave prognosis, Dr. Francis Minot saw him with me to-day. He confirmed Dr. Wyman's prognosis. At his suggestion pilocarpine subcutaneously was tried, but its effect was not characteristic but quite depressing.

Saturday, November 4th. More feeble. Very restless. Less cough. Bad night. Vomiting less. No urine through day or night. No appetite. Urinous odor to breath still very marked. Skin clammy and sticky. No stupor. Mind very clear. No puffiness of face or hands. No anasarca.

Sunday, November 5th. Very restless. Pulse feeble; skin very cool; sinking rapidly. Passed no urine. No stupor, no disturbance of vision. Mind perfectly clear up to fifteen minutes of death. He said he felt as if he was going to have a discharge from his bowels, and started up and was held up by the nurse for an instant; had a large thin discharge, then was laid down, and died after a slight convulsion, in which he passed several ounces of urine.

Autopsy November 7, 1882, by Dr. W. W. Gannett, about forty-eight hours post mortem.

Body medium size, poorly developed, somewhat emaciated. Lividity of dependent portions. Rigor mortis present. Diaphragm, both sides, on level of upper border of sixth rib.

Pericardium contained a few cubic centimetres clear fluid. Pericardial surfaces not remarkable.

Heart of the usual size. Left ventricle contracted and empty. Right ventricle and auricle moderately distended with partly coagulated blood. Aortic valves sufficient; mitral admitted tips of three fingers; tricuspid, tips of four. The valves, cavities, and muscular substance showed nothing unusual.

The left pleural cavity contained 750 cubic centimetres (by estimate) cloudy fluid; both pleural surfaces had lost their glance, and were covered in many places with a thin, fibrinous false membrane.

The left lung partially retracted; upper lobe pale red; lower lobe dark red, non-crepitant, atelectatic. On section, surface of lower lobe not remarkable; of lower lobe showed a dark-red carnified surface, in which were several grayish, slightly granular nodules, varying in size from a dried pea to a cherry stone. On squeezing cut surface, numerous large and small drops of thick pus appeared.

The mucous membrane of the bronchi deeply reddened, injected, and covered with a layer of puriform fluid.

The pleural surfaces on the right side free from adhesion; the pleural cavity contained no fluid; the pleural surfaces showed nothing unusual.

The right lung everywhere crepitant, and showed on section nothing remarkable.

The spleen slightly enlarged, of the usual color and density. On section, trabeculae distinct; follicles indistinct; pulp slightly increased in amount, of usual firmness.

The kidneys enlarged about one half in size, of a dark reddish-blue color; usual density. Capsule readily detached, leaving a smooth surface beneath. On section, cortex about one half thicker than usual. The whole cut surface presents a dark-red color, both cortex and pyramids being affected, though the latter somewhat the darker. In the cortex the region of the straight tubules dark in color and indistinct; the region of convoluted tubules here and there distinct, with paler, more opaque streaks.

The glomeruli indistinct, except when surrounded by the opaque convoluted tubules.

The mucous membrane of the pelvis of the kidneys showed nothing remarkable.

The liver of the usual size, color, and density, showing on section nothing remarkable.

Bile ducts pervious. Aorta not unusual.

Microscopic examination of the kidneys, *fresh*, showed slightly granular condition of cells of convoluted tubules; many of cells of convoluted tubules contained also fat drops. Overflowing of the vessels with blood, with numerous hæmorrhages into the tubules.

Microscopic examination hardened kidney. Marked thickening of the capsules of glomeruli with cell proliferation of same. Glomeruli for most part showed increase of the nuclei and an apparent fusion of the loops; for most part the coils of the glomeruli contained but little blood, in some places, however, they were injected. Numerous hæmorrhages into the free space between the glomerulus and its capsule. Here and there round-cell infiltration of the intertubular connective tissue. The vessels of the kidney distended

with blood throughout, also numerous hæmorrhages into the convoluted tubules of the cortex and into the straight tubules of the pyramids. Numerous epithelial casts observed.

Diagnosis. Recent pleurisy with effusion. Acute broncho-pneumonia. Limited atelactasis of lung. Purulent bronchitis. Acute hyperplasia of spleen. Acute diffuse nephritis, hæmorrhagic variety, with capsular glomerulo-nephritis.

CLINICAL REPORT ON CASES OF LACERATED CERVIX, FROM PRIVATE PRACTICE.¹

BY JOSEPH H. WARREN, A. M., M. D.,

Physician to the Massachusetts Home for Intemperate Women.

A CASE OF UTERINE AND OVARIAN TUMOR. OVARIO-TOMY.

LATE in the autumn of 1880 I was called to see a refined and accomplished American lady, — Miss F., — a native and resident of Maine, twenty-seven years of age. Her history was as follows: About two years previous to this time she had fallen from a hammock to the ground, and soon began to complain of pains in the head and spine, especially in the lumbar region. There was great tenderness over the upper lumbar and lower dorsal vertebræ. Menstruation became very irregular and painful, being sometimes profuse and at other times scanty. She was troubled with leucorrhœa and constipation, except that during her monthly periods she often had a diarrhœa for a few days. Micturition was frequent, and was attended with more or less pain and smarting of the bladder. Her sleep was disturbed by erotic dreams and frequent emissions. It should be said that in early life she had acquired the habit of masturbation, but had abandoned it as soon as she became old enough to realize its baneful influences.

Her general appearance was good and actions sprightly. Ordinarily she was fond of company and conversation, but at times, and especially if alone, she would be low spirited, morose, and disposed to sigh and cry. These periods of depression increased in frequency and intensity as time went on, and as there was a history of insanity in the family it was feared that she too was losing her mental vigor. During this time she had been treated by her family physician for a uterine tumor with anteversion, and by a physician in Augusta for misplacement, retroversion with ante-flexion, and a tumor of the fundus of the uterus. She had also complained of flatulence and dyspepsia, although for a few months, by strict attention to diet, these symptoms had abated. She had no great thirst, and her only abnormal appetite had been for chalk and slate pencils in her school days. But she now complained of a choking sensation, and of pain in the left side over the slightly enlarged spleen, and of a pain over the left ovary which was constant, but aggravated so decidedly at her menstrual periods as to amount to an ovaritis. She had taken no exercise for some time either within doors or in the open air except now and then a short ride in a carriage, because walking induced more pain in the pelvic region and more frequent micturition.

On January 1, 1881, with the assistance of Dr. W. Everett Smith, of Framingham, I made an examination of the patient under ether. Through the abdom-

inal walls it was easy to feel distinctly the outlines of a uterus enlarged to the size of a four or five months' pregnancy. The os and cervical canal were so contracted that the smallest uterine probe was at first introduced with difficulty, but after some perseverance it was passed, and a larger one easily followed. The uterus was in a position of retroversion; the probe passed in about five inches and was easily moved around. By bimanual and rectal examination we found an absence of adhesions as well as of ovarian disease.

There had been, it will be remembered, no history of any excessive uterine hæmorrhage, and nothing to indicate a uterine fibroid except a gradual increase of size for about two years. But the last twelve months had been marked by a more perceptible increase, together with a greater amount of pain and suffering, so that at the time of examination the general appearance of the uterus was, to use a homely comparison, not unlike a large crook-necked squash with a very long neck. By passing the large uterine probe within the uterus the posterior wall could be felt of normal thickness by the finger in the rectum; while by pressing the hand upon the abdomen the anterior wall of the uterus seemed greatly thickened. No enlargement of either ovary could be detected. The abdomen at the umbilicus measured thirty-eight inches; but whether this increase was due to a fibroid tumor or to a simple hypertrophy of the uterus, I was not sure then and am not now.

The following day I examined the urine. The specific gravity was 1023, it later became 1026. There was an abundance of urates, earthy phosphates, and bladder epithelium, but no pus or blood corpuscles. There was no swelling of the feet or ankles. I prescribed for her sulphate of quinine four to five grains, with a half teaspoonful of compound licorice powder night and morning, and ten grains of bromide of sodium after dinner and supper. For the uterine tumor I began to use clay from New Jersey, similar to the kiud that Dr. Hewson mentioned in the Transactions of the American Medical Association for 1880. I mixed it into a soft mass with warm water and spread it on strips of muslin about 2.5 inches wide, with which I thoroughly covered the abdominal walls. These dressings were removed every five or eight days, when by molding a thin strip of sheet lead over the abdomen from the symphysis pubis to the ensiform cartilage the contour of the abdomen could be watched. At the same time the size of the abdomen could be determined by measuring the waist and abdomen at the umbilicus and crest of the ilium.

In May, when this treatment had been continued about four months, the patient measured twenty-two inches at the waist and twenty-six at the umbilicus; the probe could be passed into the uterus only the normal 2.5 inches; the flexion and elongated cervix had disappeared, and the uterus seemed soft and virgin like. The bladder trouble had all subsided, the patient had gained in weight; her buoyancy of spirits returning, she had been able for two months to take exercise in the open air without difficulty, and in this happy state returned to her home.

But this was far from being the end of this most interesting case, for soon after her return home she began again to complain. We, however, who had seen her in apparently such good health, were inclined to think that her new complaints arose from the discontent and loneliness she naturally felt after a winter in the

¹ Concluded from page 200.

city, and for some time could not believe that she was really so sick as her family represented her to be.

It seems by her account, when she presented herself again for treatment late in the fall of 1881, that at the time of her return home she thought she strained herself while riding in the cars, as she felt sore around the hips and could not walk without pain there. Also in about six weeks after her return she noticed that she began to enlarge over the right side of the abdomen, until in eight months she was as large as when she first came under treatment. She had the same old symptoms, — headache, backache, melancholy, dyspepsia, frequent micturition, and pain over left ovary, but menstruation nearly normal. Otherwise than this she seemed physically stronger than she had been in January.

On December 22d, with Drs. H. O. Marcy, Nelson, and C. E. Warren, we again etherized her, and found the uterus normal, but upon the right side we found an ovarian tumor of large size. The left ovary was also thought to be enlarged. We recommended the removal of the tumor, and the patient seemed very impatient for the operation.

Accordingly, after a tonic treatment to remove the dyspepsia, I performed the operation of ovariectomy on January 18, 1883, assisted by Drs. H. O. Marcy, Nelson, Bancroft, Smith, and C. E. Warren. Antiseptic precautions were taken. I made my incision about five inches long in the median line, and found the tumor to be multilocular and pretty free from adhesions. The largest cysts were filled with a very dark fluid, of the color and consistency of malt. I tapped them with Fitch's trocar. The smaller cysts were filled with a pearly white fluid resembling boiled starch. Since they extended high up in the abdomen, even to the ensiform cartilage, there was great danger of puncturing the stomach and intestines by the trocar, as Thomas points out in his treatise. I feel confident that with Wells' or Fitch's trocars I should have been in great danger both of puncturing the intestines and of tearing the thin walls of the cysts and allowing the fluid to escape into the abdominal cavity. But I had with me a small trocar, No. 36, of my own device, with a revolving point, and all present were highly pleased with its use. It passed readily into the cysts without jerking or jumping, and when in one cyst could be passed directly into an adjoining one with perfect safety and great ease.

The tumor and its contents weighed 13.5 pounds, a fair sized tumor for a girl whose entire weight was less than one hundred pounds. The pedicle was ligatured with carbolized animal ligatures obtained from the tendons of the moose, and kindly furnished me by Dr. Marcy; but before returning the stump into the cavity I stitched the end with fine carbolized catgut of Lister's preparation. Being careful that all blood and fluid were sponged from the abdominal opening, I brought the integument together with seven stitches and applied a thick dressing of thymolized cotton.

Her temperature immediately after the operation was 97.4° F., and pulse 60, but by nine o'clock in the evening the temperature was 100.4° F., and pulse 108. She complained of great abdominal pain in the right iliac fossa, for which small subcutaneous injections of morphia were repeatedly given. On the third day her menses returned and the temperature and pulse accordingly rose to 101.6° F. and 112 respectively. But they speedily subsided to the normal point, and so con-

tinued until the fourteenth day, when the patient became hysterical and almost unmanageable. By her violent motions she thus succeeded in superficially opening the abdominal incision from which on the twelfth day four stitches had been removed. I soon called in consultation Dr. C. P. Bancroft, Superintendent of the New Hampshire State Insane Asylum, and tried in succession the bromides, hyoscyamus, and morphine with only partial success. I then called Dr. Jelly, late Superintendent of the McLean Insane Asylum, and returned to the trial of hyoscyamus.

The patient gradually became more quiet in her manner, and seemed to justify our opinion that she would ultimately regain her mental condition. Menstruation returned at the proper time without any increase of temperature or disturbance of the system, so that in about six weeks after the operation it was thought best to take her to the Insane Asylum in Augusta, Me., near her home. She endured the journey well, but the asylum was full, and she was therefore attended at her home by Dr. Harlow, the Superintendent. She gradually recognized her surroundings, and for a brief space became mentally clear. All abdominal symptoms had disappeared, but in May, four months after her operation, she suddenly and unexpectedly died from pneumonia.

CHRONIC ABSCESS OF THE MAMMARY GLAND.¹

BY CHARLES E. GRANDALL, M. D., PORTLAND, ME.

History. Was called by Mrs. R., aged twenty-five, to see her in regard to an enlargement of her right breast. Found her to be a small woman, weighing about one hundred pounds, and of marked strumous diathesis. She had been married five years, but had never been pregnant. Her family history was given substantially as follows:—

A long time previous to the death of her father, he had what she described as a humor; said that it was confined mostly to his limbs, and was called "Syra-cuse humor." Her mother is still living, in fair health. Her sister, next younger, of light complexion, has rather delicate health, while a still younger sister is deaf and dumb, and in addition has slight curvature of the spine. Two of her mother's female cousins have died from cancer.

Was informed that the enlargement of the mammary gland, for which she sought advice, first appeared about seven weeks previous. The first that she noticed was a small sore spot in the median line of the right breast, about an inch and a half above the nipple. Gradually a small tumor seemed to form, which developed to about an inch or more in diameter, and was of rather dense consistence. This remained without perceptible change for a couple of weeks, and then seemed to soften, and, as it did so, her breast began to enlarge, until it was at least twice its natural size. After it attained this size, which was about five or six weeks from the initial stage, she did not observe much change, unless, perhaps, the breast became harder. During all this period there were no additional marked local symptoms, such as pain, throbbing, discoloration, or heat.

During the two weeks previous to her coming under observation, she had experienced what she described

¹ Report of a case read before the Portland Medical Club.

as a smarting sensation, having its location between the outside of the gland and the axillary space. There had been also a remarkable absence of acute constitutional symptoms, such as chills, fever, disturbances of circulation and nervous system.

There were evidences of impairment of general health, but doubtless due in a large degree to an extremely unhappy mental state. She and her friends had concluded that she was afflicted with cancer of the breast, and she had passed into the despondent mood so common among the victims of that wretched disease. Moreover, she had consulted some physician in her neighborhood, and he unreservedly pronounced the tumor to be cancerous in nature.

Remarks. From the history I concluded that my patient was afflicted with a chronic abscess of the mammary gland, and so expressed myself; but on examination found some symptoms that rendered a diagnosis difficult.

It was impossible to detect true fluctuation, but there was one point about the size of a dime which, under pressure, seemed to feel slightly softer than elsewhere. Moreover, the gland seemed too resisting to contain simply a cavity filled with pus, and there was a decided enlargement of the lymphatic glands of the axillary space. These symptoms, so suggestive of malignant disease, gave rise to some doubt in diagnosis, and therefore the patient was invited to accompany me to Dr. Gordon's office, to the end that his opinion might be obtained.

Doubt still lingering, we concluded to insert an exploring needle into the point before mentioned, which seemed to offer least resistance.

Upon doing so our exploration was rewarded by the tardy appearance of a thick, yellowish-colored pus. Soon after, a free incision was made, which was promptly followed by a copious discharge of pus and blood.

Chronic abscess of the mammary gland, so far as I can learn, is very uncommon. It is doubtless safe to say that one will see many cases of phlegmonous abscesses to one like the case under consideration. The predisposing cause is that mysterious condition vaguely termed "struma," or "scrofula." Patients thus afflicted belong to that class of whom Professor S. D. Gross says, "Nature has stamped with a peculiar diathesis, or state of the system, rendering them prone to phthisis, coxalgia, caries of the spine, and kindred maladies."

Of the exciting causes there are several, the chief of which are injuries, like blows, contusions, inflammations, and obstructions of the lactiferous ducts. In the case now referred to there was no remembrance or evidence of exciting cause.

The clinical history of a case has been briefly described as follows: "The disease usually begins in the form of several hard lumps, which, gradually coalescing, at length unite into one solid mass of irregular shape and of firm consistence, sometimes involving only a portion of the breast, and at other times the entire organ. Occasionally the glandular structure escapes completely, the morbid action being confined exclusively to the connective tissue around, behind, or in front of the breast. By and by a process of softening begins and, steadily progressing, a large accumulation of pus occurs, pressing upon the parts in all directions, and in time fluctuating distinctly under the finger.

"Marked enlargement of the subcutaneous veins usually attends, especially where the disease is of long

standing; but there is no discoloration of the skin, and seldom any severe pain; merely, perhaps, a sense of weight and uneasiness.

"The general health is not materially affected, and there is no involvement of the surrounding lymphatic glands."¹

As a point of clinical interest I wish to repeat that in this case the lymphatic glands of the axillary space on the right side were markedly enlarged, and it was that fact which caused especial perplexity in forming a diagnosis. Their enlargement was probably due to either pressure or irritation, for they began to decrease in two or three days after the abscess was evacuated, and ultimately resumed their normal size.

Besides the surgical treatment in this case, a systematic medical treatment was pursued for three months or more. It consisted of tonics, stimulants, best blood-making food, and plenty of out-door recreation. As a result, the discharge gradually ceased, the gland returned to its natural size and consistency, the wound closed, and the patient declared herself to be in better health than she had been for a long time.

RECENT PROGRESS IN ANATOMY.

BY THOMAS DWIGHT, M. D.

MEASUREMENTS OF BODIES OF VERTEBRÆ.²

DR. R. J. ANDERSON has published a series of measurements that may prove of practical use in medico-legal studies, and which are of a good deal of scientific interest. Some of the observations are deduced from the measurements of more than fifty spines. The author draws the following conclusions:—

"(1.) The anterior vertical diameters of the vertebræ, from the first dorsal to the third lumbar inclusive, are less than the posterior.

"(2.) The anterior vertical diameter of the fourth lumbar is equal to its posterior, and in the fifth is greater.

"(3.) The transverse diameters of the bodies increase from second cervical to second dorsal, then diminish to fifth dorsal, then increase to last lumbar.

"(4.) The antero-posterior diameters increase gradually from third cervical to third lumbar, and then diminish.

"(5.) The non-equivalence of the lateral parts of the bodies is generally observable from the seventh to the tenth dorsal, and may extend to the third and eleventh" (dorsal?) "vertebræ."

The height of the anterior surface of the vertebral bodies tallies very closely with the reporter's measurements in the identification of the human skeleton. Dr. Anderson is inclined to attribute the lateral asymmetry of the bodies in the dorsal region to the lateral curvature of the spine, but the peculiar flattening of the left side of the bodies seems to us to show conclusively that it is due to the pressure of the aorta. Unless we are mistaken this difference is usually to be seen in the fifth dorsal.

THE LINES ON THE ARTICULAR SURFACE OF THE LOWER END OF THE FEMUR.³

The lines in question are thus described in the last

¹ System of Surgery, Gross.

² Journal of Anatomy and Physiology, vol. xvii., part 3, April, 1883.

³ Prof. Jacob Heiberg, Archiv für Anatomie und Entwicklungsgeschichte. 1883.

edition of Quain's Anatomy: "One large articular surface coated continuously with cartilage extends over both condyles, but, opposite the front of the intercondylar fossa, it is divided by two irregular, slightly marked, transverse grooves into three parts, an elevated surface on each side for articulation with the tibia, and a grooved anterior surface for the patella." The generally accepted theory of the origin of these grooves is the one first proposed, we believe, by Henle, that they are made by the borders of the semilunar cartilages in the upright position. Professor Heiberg, of Christiania, has undertaken to refute this view. He points out that the external of these two lines very often is convex posteriorly, and, moreover, that the lines are better marked in young subjects than in old ones, both of which observations are inconsistent with the theory. He also performed the following experiment, which showed that the lines do not correspond with the semilunar cartilages: The knee-joint of a fresh leg was put in the extended position and the capsule very carefully opened just below the patella. The position of the transverse ligament connecting the semilunar cartilages was marked by a slight cut on the femur.

The tibia was then removed, the semilunar cartilages being left, and a plaster cast was taken of the lower end of the femur, which showed that the semilunar cartilages cross the lines in question and cannot possibly produce them. Professor Heiberg gives an excellent illustration of the position the cartilages occupy in relation to the femur. He then points out that these same lines are found in several orders of mammalia in which the knee is habitually more or less flexed, and in which it is impossible they should be the result of pressure through the tibia. He refers also to the well-known fact that in many of these animals the knee-joint consists of two or three more or less completely separated compartments, and suggests that these lines in man should be considered rudimentary organs representing the lines marking these partitions.

A NEW RULE OF EPIPHYSES OF LONG BONES.¹

This rule applies merely to the order of appearance of the centres of ossification in the epiphyses. For the long bones the well-known rule that the epiphysis towards which the nutrient artery runs is the last to appear and the first to unite is convenient for the individual bones (in spite of the exception the fibula presents), but of course it gives no clew to the relative dates of the appearance of ossification in different bones. Mr. Sutton thinks he has found that those epiphyses which are largest in proportion to the shafts of the bones they are to join are the first to show ossification. Thus the two earliest are the lower end of the femur and the upper end of the tibia. The lower end of the fibula by this rule precedes the upper. The femur is a good example. The lower end being much the largest epiphysis ossifies first, then the head, the great trochanter, and finally the lesser trochanter.

It seems that this rule does not admit of very accurate application in all cases, but we believe the idea is a new one, and it deserves more study, especially in comparative anatomy.

¹ Journal of Anatomy and Physiology, vol. xvii., part 4, July, 1883.

THE TRUE SIGNIFICANCE OF THE TRANSVERSE PROCESS OF THE LUMBAR VERTEBRÆ.²

Professor Holl has undertaken the study of the significance of the parts of the vertebræ by means of microscopic sections of young human embryos. Such a method is undoubtedly a good one, far superior to fanciful comparisons of adult specimens, but to be perfect the method should also include the study of the embryonic forms of lower animals. Holl's work, however, is very excellent. He shows the development from the side of the body of the vertebræ of what he call the *processus lateralis*, from which spring the laminae, and in which the rudiments of the transverse processes and ribs are contained. He shows that originally the cervical dorsal lumbar and sacral vertebræ have similar lateral processes. A glance at his plates shows how in the early stages the transverse foramina of the cervical vertebræ correspond to the space between the neck of the ribs and the vertebræ in the dorsal region. Holl shows that the transverse processes of the lumbar vertebræ contain the undeveloped rudiments of ribs.

THE EFFECT OF ROTATION ON THE TOPOGRAPHY OF THE NECK.³

We regret that we have not had an opportunity of seeing this interesting paper, which we know through an abstract in *Schmidt's Jahrbücher*. The change of the relations of important structures owing to the movements of the body is a very interesting question. Henke points out that in strong rotation of the head to the left, for instance, the right sterno-mastoid becomes almost vertical, the mastoid process being nearly above the sternum, and that if the head is then turned the other way this process almost reaches the posterior median line. Thus in rotation the upper end of each of these muscles sweeps through nearly half a circle, and one would naturally think that the deeper parts share in this motion with gradually decreasing freedom from above downwards. This, however, is not the case. The chief motion is of the atlas and cranium, and even in the soft parts there is a distinct line separating the parts that rotate with the head from those that remain at rest with the neck. This line passes just below the hyoid, which, with the cavity of the mouth and the epiglottis, follows the head, while the larynx remains at rest. We must say here, in parenthesis, that we cannot believe that Professor Henke means to deny *all* rotary motion of the cervical spine below the atlas, and if any occurs it is hard to conceive that the soft parts should not share it to at least some extent. Be this as it may, we do not doubt that there is, as Henke states, a sudden transition point between little or no movement below and much movement above. It is therefore evident that the relations of the sterno-mastoids to the larynx must vary considerably. According to Henke, when the head is turned to one side the anterior muscle may almost reach the median prominence of the thyroid cartilage, while the other leaves the side of the larynx quite uncovered. The common carotid with its continuation, the internal carotid, and the accompanying structures, take part in this movement. The side of the atlas that is brought forward carries these structures with it away from the

² Holl, Sitzungsberichte der Academie der Wissenschaften, Wien, Band lxxxv. 1882.

³ Festgabe zur Anatomie und Embryologie. Festgabe für Professor Henle. Bonn. 1882.

transverse processes of the cervical vertebræ. The loose connective tissue beneath the posterior border of the muscle fills the vacancy behind the vessels. They are no longer within the superior carotid triangle, being covered by the sterno-mastoid. On the opposite side the carotid is exposed, and its pulsation can be felt or even seen in thin persons.

The custom of celebrating the anniversaries of distinguished anatomists and physiologists by publishing a collection of monographs, while gratifying, no doubt, to all immediately concerned, is very inconvenient to the public, as these publications are necessarily expensive, and enjoy but a very limited circulation. This paper, from a testimonial to the great anatomist, Henle, is a case in point.

SEXUAL DIFFERENCES IN THE SURFACE OF THE BRAIN.¹

Very little notice has been taken of the influence of sex in the size and shape of the brain, and more especially the convolutions, in spite of the great attention the subject in general has received. We, for once, therefore, are glad to see the historical section near the beginning of the paper before us, which gives a brief account of what has been done. Nearly thirty years ago Huschke maintained that differences in the convolutions of the male and female brains could be detected. He stated that as a rule the fissure of Rolando was more nearly vertical in woman than in man, so that the distance of the top of the fissure from the posterior end of the brain was relatively greater in the former. Consequently in man the frontal lobes, and in woman the parietal, were relatively the larger, and the female brain was rounder. Recently Professor Rüdinger, of Munich (with whom Dr. Passet has been studying), has taken up this subject, and has turned his attention to foetal brains. He has stated that in most male foetal brains the frontal lobes are more massive, broader, and higher than in female ones; that the convolutions in the female foetus of seven or eight months are much simpler than in the male. He finds, also, that the fissure of Rolando is more oblique in the male than in the female, and consequently there is more cerebral matter in front of it in the former and behind it in the latter. Dr. Passet has devoted himself to the study of these questions, and has made careful measurements of thirty-seven brains (twenty male and seventeen female). His method seems very thorough, but we skip the details. His results in the main confirm Huschke's observations. The fissure of Rolando is more oblique in the male than in the female, and is also longer and more curved. It lies both absolutely and relatively further back in man; in other words there is more cerebral matter in front of it. The male brain is pretty clearly longer, broader, and higher than the female, and, as the same is of course true of the skull, it follows that the relations of the chief fissures to the sutures are not materially different in the sexes. Still, because the male brain is the larger, it follows that the fissure of Rolando is more distant from both the coronal and lambdoidal sutures than in the female. The parieto-occipital is usually in front of the lambdoidal suture in both sexes, but is likely to be more distant from it in the male.

We should not omit some mention of a simple and yet original method employed by Rüdinger, which is the comparison of the brains of twins of different sexes.

DECUSSATION OF NERVES IN THE LARYNX.²

It has been recently shown by Mandelstamm that the laryngeal nerves of the guinea-pig cross the median line, and Dr. Weinzwieg has been interested to ascertain whether any analogous arrangement is to be found in the human larynx. He has found two nerves running in the median line in the mucous membrane of the back of the larynx, one downwards from above, one upwards from below, and each giving off lateral branches. They are very small, the upper, which is the larger, being barely visible to the naked eye. They have been studied, magnified, the mucous membrane having been removed and made transparent by caustic potash. Hence it is not always easy to trace these nerves to larger trunks, but from some arrangements that have been observed it seems plausible to suppose that at least the upper one is, or may be, formed by the union of two lateral nerves. The microscope shows that the branches contain some fibres crossing from the other side. It should also be mentioned that anastomoses are sometimes found between the upper and the lower nerves. The author is inclined to trace the upper nerve to the superior laryngeal and the lower to the recurrent, and points out that there is now a disposition to relinquish the view that the latter is purely motor, and to believe that it sends minute ramifications to the mucous membrane.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SURGICAL SECTION.

ALBERT N. BLODGETT, M. D., SECRETARY PRO TEM.

APRIL 4, 1883. Meeting called to order at 8.05 o'clock. DR. R. M. HODGES in the chair.

The first paper was upon the subject of

HÆMORRHAGE FOLLOWING TONSILLOTOMY,

by DR. J. W. OTIS. Before presenting the paper the reader made some general remarks concerning the regional anatomy of the pharynx and the nominal relations of the tonsil to the various blood-vessels and other important structures in its vicinity, and to illustrate the position of the parts, Dr. Otis exhibited four very beautiful anatomical preparations of that portion of the neck, in which the blood-vessels had been injected and the other organs stained with various colors so as to make them more distinct. The whole preparation was then carefully embedded in paraffine, which formed a firm and elastic white groundwork upon which the anatomical features of the specimens were sharply visible.

DR. HODGES, in introducing the reader, called attention to the care and skill with which the various structures about the pharynx had been prepared in the dissections, which he said related to an important region.

Upon the conclusion of his paper, DR. OTIS stated, in reply to a question, that his researches had led him to believe that whenever it is necessary to excise the tonsil, the tonsillotome should be the instrument employed. If this cannot be done, then the scissors or knife, or probe-pointed bistoury may be used. Several

¹ Passet, Archiv für Anthropologie, Band xiv. 1882.

² Weinzwieg, Sitzungsberichte der Academie der Wissenschaften, Wien., Band lxxxvi. 1882.

applications may be sometimes prescribed with advantage, but when the tonsil is very large no form of topical treatment is of any avail. If such remedies seem desirable, the best applications for astringent effect are glyceride of tannin, tincture of chloride of iron, and tincture of iodine. There is no call for internal medication, although iodide of potassium has been recommended and extensively employed in these cases. The form of tonsillotome most to be recommended is that of McKenzie, as it is firm and strong, and has no hooks, which may possibly draw the tonsil too far within the guillotine and do injury to other parts, or provoke hæmorrhage. The tonsil should not be excised in childhood unless urgent reasons exist for so doing, as these organs subside at the age of puberty and frequently never give any further trouble.

DR. H. OSGOOD said he had noticed this, and had thought of writing a book upon it. He mentioned the case of a lady whose tonsils were studded with fibrinous plugs, which were diligently removed by opening the tissue from one crypt of the tonsil to another; and he now treats similar cases in this manner. The depressions are then swabbed with cotton saturated with nitric acid or tincture of iodine and carbolic acid. In cases occurring since, he has always been able to notice a reduction in the size of the tonsil in three months.

DR. HARLOW stated that he had removed the tonsil in children with no bad results in two cases. The patients afterward became singers. Tincture of iodine was first faithfully employed locally, but did not reduce the size of the organ. He has also employed solutions of nitrate of silver, but now prefers chemically pure nitric acid, under which the tonsil generally becomes smaller. There is some danger from hæmorrhage in operating with the tonsillotome, as was observed in a case some years ago in which the tonsil was excised and an alarming loss of blood supervened, which was finally controlled after some hours by pressure from the outside and ice in the throat.

DR. F. H. HOOPER spoke of the distance of the tonsil from the carotid artery, and stated that Dr. Delavan, of New York, has shown that the edge of the tonsil is 1.5 centimetres from the wall of the internal carotid artery, and two centimetres from that of the external carotid. The tonsil is surrounded by a mass of connective tissue which protects the blood-vessels.

DR. S. W. LANGMAID remarked that the question of operation upon the tonsil always involved the existence of dense indurated tissue. In this condition the blood-vessels do not contract as is usually the case, but the bleeding ends are held open by the induration in their vicinity and an alarming hæmorrhage may more easily take place. This was the cause of the bleeding in Dr. Leffer's case.

DR. ELSBERG has operated upon the tonsil thousands of times and has never had serious accidents. Hardly another surgical procedure, except cutting corns, is more safe or more simple. In adults who are calm and fearless the bistoury may be used with perfect safety, but this cannot be so easily done in children, and the tonsillotome then becomes a blessing. With the Fabnestock instrument the tonsil is quickly and easily removed. In adults this instrument cannot be employed. The tonsil is so dense that the tonsillotome would not be strong enough to cut it. The amount of force employed in the operation is generally much too great. The tonsil should be supported by pressure

from the outside and a very slight amount of force is generally sufficient to excise the organ. The nearest blood-vessel is the ascending pharyngeal artery, but this cannot be wounded without cutting through the constrictor muscle. Of course in a patient with a hæmorrhagic diathesis, a so-called "bleeder," there might be an alarming or even fatal loss of blood, as would follow the extraction of a tooth.

DR. DEBLOIS remarked that a very useful procedure in case of a very large tonsil is the employment of a snare made from a steel wire, which will sever any tissue which a knife will cut. The pressure upon the tonsil upon the outside to support it during operation may introduce elements of danger, besides which, too much of the tonsil may be removed. The tonsil has a function in the human economy, and too much of its tissue should not be removed. There is no danger from the operation unless too much of the organ is included. With a small tonsil and a large guillotine, aided by pressure from the outside, large vessels may be wounded in the operation. In one case under his care there was serious hæmorrhage for an hour.

In answer to Dr. Cheever, DR. LANGMAID stated that by excision of the tonsil the voice is improved for singing.

DR. CHEEVER then stated that defective vocalization may be produced by excision of the uvula, and mentioned a case seen by himself in which the uvula had been removed by an operation, with the result of serious interference with the voice in singing. One cause of hæmorrhage of the tonsil which has not been touched upon is that which results from incising the tonsil in search of pus when the organ is the seat of abscess. This affection is not very common, but unfortunately it is very apt to recur frequently in an individual once affected with it, and it is always accompanied with much disturbance and great pain. The safest place to puncture the organ in search of pus is through the upper part of the soft palate. Often no pus is found, and when a spontaneous evacuation of pus follows it is frequently not through the incision made by the surgeon. Dr. Cheever always employs the tonsillotome in the removal of tonsils and has never used the bistoury, and has never experienced any serious accidents in the operation. He has strong faith in the abortive treatment of abscess of the tonsil by means of strong astringent applications to the organ. He prescribes tannin, myrrh, and the compound tincture of benzoin.

DR. LANGMAID stated that abscess of the tonsil is frequently only an abscess of the connective tissue about the tonsil, and that sometimes it will point in three days and sometimes requires ten or twelve. The distress is very great, and when it points it does so at a point very near the last molar tooth in the lower jaw, and often an incision at this point before pointing of the abscess will afford immediate relief from the pain.

In reply to Dr. Hooper, DR. CHEEVER stated that he did not know whether the locations of the so-called abscess of the tonsil were in the tonsil or in the connective tissue about it.

DR. LANGMAID remarked that abscesses often occur in the follicles of the tonsil, the so-called "follicular abscesses," and are subject to frequent recurrences and call for operative treatment.

DR. DEBLOIS spoke of the reproduction of the tonsil, and mentioned a case in which the tonsil was

excised six years ago, since which time Dr. DeBlois has also excised the same tonsil, yet at the present time the organ is so large as to require excision again. It is a common belief among patients that the tonsil grows again after excision.

DR. C. D. HOMANS said that he regarded tonsillotomy as one of the most beneficial operations in the entire domain of surgery. He has operated a great many times on children and has never had the slightest trouble or any indications of danger. In one family of eight children the tonsils were excised in seven of them, and every child became a singer. The hæmorrhage is always trivial, and never amounts to anything worth noticing. In the case of a patient who was a "bleeder" the hæmorrhage was protracted, but this could not properly be set down against the operation. The knife should never be employed, as some portion of the tonsil can always be reached and removed by the tonsillotome.

DR. LANGMAID mentioned that a certain professor in Philadelphia had called attention to a fancied relation between the tonsil and the testicle, and advised against the excision of the one on the ground that the function of the other might be destroyed and the virility of the patient would thus be obliterated, or if the subject be a child, this power might never be developed. The only experience upon which the statement seems to rest, is based upon one case in which a man who had had his tonsils cut never became a father, although married for many years. In consideration of the many causes operating to produce this effect in either sex, it is yet hardly appropriate to lay so serious a charge to a simple and insignificant operation in a remote part of the body.

DR. HODGES stated that no well-known case of serious hæmorrhage from tonsillotomy has occurred in Boston within twenty-five years. The operation was formerly performed much more frequently than now, probably three times as often as to-day, both in hospitals and in private practice. He said that he fully agreed with Dr. Homans as to the great benefit which often follows the operation in children, cases of anæmia and weakness in frail and pigeon-breasted children often improving in a most astonishing manner when nothing seemed to do any good before the tonsils were cut. Often such children became very rugged and strong. If the operation is not done in childhood there is frequently no occasion for it afterward, as the organs gradually subside at the age of eighteen or twenty years. As an example of the frequency of the operation, we have the experience of Dr. Elsberg, who states that he has removed the tonsil in eleven thousand cases, which is an astonishing announcement. This would amount to 444 operations every year, or more than one tonsil each and every day for *twenty-five years*. The best means for removing the tonsil is the guillotine tonsillotome, which does the work better and provokes less hæmorrhage than any other method known. The instrument works better if it is dull, as it probably crushes the tissues and thus prevents hæmorrhage by acting somewhat as an *écraseur*. The late Dr. Mason Warren had a large experience in this surgical procedure, and never used to have his tonsillotome sharpened. An instrument operated by *pushing* is far more useful than one in which the blade must be *pulled*. Dr. Hodges has no experience in the use of the bistoury, and should never employ it in this operation. A surgeon requires a *set* of tonsillotomes. The attempt

to use an ill-fitting or ill-adapted instrument is unsatisfactory to both surgeon and patient.

DR. M. H. RICHARDSON presented a paper upon

RUPTURE OF THE LIGAMENTUM PATELLÆ,

presenting a specimen which had been found in the dissecting room, and giving a summary of all known cases of this lesion. Dr. Richardson attached a great deal of importance to the lateral fibres from the borders of the patella and from the tendon of the quadriceps extensor, which spreading out over the lower part of the knee-joint in a fan-shaped manner were attached to the head of the tibia, and afforded great strength and prevented displacement of the patella to a greater distance than half an inch, even if the ligamentum patellæ were completely divided. An anatomical preparation of the knee-joint was then properly mounted so as to show the normal relations of the parts, and it was found that the rupture of the ligamentum patellæ must be accompanied by a laceration of these fibres from the sides of the patella forming a part of the capsular ligament, extending from the internal condyle entirely across the front of the knee to the external condyle, a rupture of at least seven centimetres in length, before the patella became sufficiently loosened to be drawn upward by the contraction of the muscles of the thigh.

DR. S. J. MIXTER saw a case of supposed rupture of the ligamentum patellæ, one year after the accident, when the patient suffered the same accident in the other limb while walking. The entire patella was drawn upward a distance of seven centimetres, and was discovered with great difficulty, as the patient was very fat. Above the tubercle of the tibia was a small fracture of the edge of the tibia or a portion of the patella. The patient was almost helpless, requiring a crutch and a cane in addition to a firm supporting bandage.

DR. CHEEVER has observed two cases of rupture of the patellar ligament. One case occurred in an old gentleman whom he found sitting on a chair unable to flex or extend the leg. The contour of the knee closely resembled the dissected anatomical specimens, looking as if the condyles of the femur were pushing through the skin into the world. The skin was very tight, and the entire shape of the end of the femur could be distinctly seen. The case recovered after some months with a comparatively useful limb. The second case was observed in a sailor who had suffered the injury at some former time, and was quite a surgical curiosity. The patient could swing the leg about so as to walk, and made no complaint. The patella was drawn far upward upon the thigh, and the condyles of the femur were completely exposed. The motion of the leg upon the thigh was something like that of a farmer's flail. Upon flexing the leg the condyles seemed to be coming directly through the skin. Dr. Cheever suggested that the strong lateral fibres which radiate to the sides of the knee-joint may have a great deal to do with the repair of fracture in the patella by keeping the parts in tolerable apposition. The rupture of the tendon above the patella is not a very rare accident. Dr. Cheever has had one case in an enormously fat woman, which was under treatment for some months. A large, fleshy callus was found above the patella, but even at this day the patient, though entirely well, requires the aid of a stiff supporting bandage in order to walk. The rupture of the ligament above the patella may be supposed to

heal more readily and perfectly than the rupture below.

DR. RICHARDSON mentioned the injury sustained by Dr. Bowditch as of this variety, and spoke of the entire recovery of the usefulness of the limb as supporting this suggestion.

DR. HODGES has seen two or three cases of rupture of the patellar ligament. In each case the laceration occurred close to the patella. He was struck by extensive division of the lateral ligaments, which was necessary before the patella could be drawn upward to any considerable distance from the lower fragment of the ligament. He thought this a singular and unexpected fact.

DR. A. T. CABOT recurred to the case alluded to by Dr. Richardson, in which after continued treatment by rest, bandage, and support, no repair had taken place. The depression was unchanged, and it seemed as if the infirmity were permanent. The skin over the seat of the ruptured ligament was then blistered. The first vesication was followed by an exudation which filled about half the depression occasioned by the rupture of the ligament. After the second blister the entire depression was completely filled up by a hard callus, which remained firm. After a time the stiff bandage was removed, and the patient has a very useful limb. On going up stairs the injured leg is dragged after the other, but in coming down stairs the patient puts one foot before the other in the usual manner. Dr. Cabot has also derived very beneficial results from the employment of blisters in the treatment of divided tendons in other parts of the body, especially those of the fingers. In the treatment of these injuries the use of vesicants seems to promise much more benefit than any other method now employed.

Adjourned at 10.05 o'clock.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

CHARLES H. WILLIAMS, M. D., SECRETARY.

MAY 21, 1883. DR. INGALLS in the chair.

Dr. Ingalls reported a case of

DIVISION OF THE INTERNAL JUGULAR VEIN.

The patient, some two months before entering the hospital, noticed a swelling below the left ear, which increased until it filled the parotid region. He gave up work, but did not have much pain. May 3d, a soft spot near the lower margin of the tumor was opened and some thin fluid discharged; the health was good, appetite and strength fair. May 11th, an operation was performed for the extirpation of the tumor. In the course of the operation, having laid aside the scalpel and using the fingers to draw forward the lower part of the tumor, some dark blood was seen to well up suddenly from the lower part of the wound, and at the same moment the patient died. There was no noise or click heard, such as is mentioned in connection with such cases when air enters the vein. The autopsy, by Dr. Draper, showed the following conditions: Twenty-four hours after death, rigor mortis marked. On left side of neck was a recent surgical incision three and a half inches long over the anterior edge of the sterno-cleido-mastoid muscle and nearly parallel with it; also

a counter-cut two inches long, extending posteriorly from the middle of the principal wound; the edges of these incisions being opened, a tumor was disclosed occupying the upper cervical and left parotid regions; it was very soft and friable, and was much broken up (microscopic examination showed it to be a large celled sarcoma). This new growth was mostly separate from the surrounding tissues at its lower part; it had invaded these tissues in such a manner as to distort the normal anatomical relations of this region.

Internal examination: The primary incision along the front of the body failed to show anything noteworthy about the mouths of the divided vessels; neither blood nor bloody bubbles appeared. The pericardium was normal, its visible area not exceeding the usual dimensions; when the heart was exposed, it was plainly to be seen and felt that the right auricle contained mingled blood and air; numerous bubbles could be observed through the thin wall, and fine crepitation could be felt. A small incision in the anterior wall of the right ventricle set free, at first, some loose, dark coagula, followed upon slight pressure by a mass of spumous froth intimately mingled with blood-clot. The amount of air in the right auricle and ventricle was insufficient to distend those cavities beyond their normal volume. Free incision of the right ventricle found this cavity occupied by dark, ill-formed clots and masses of bloody froth, the latter especially marked among the depressions of the columnæ carneæ and in the tendinous attachments of the tricuspid valve. The left cavities of the heart were empty, the left ventricle being moderately contracted. The structure of the organ was healthy. An elastic catheter, which was passed into the superior vena cava and directed upward and to the right, emerged through the open mouth of the divided left internal jugular vein at the bottom of the surgical wound, just below the point of division of the left carotid artery. Both lungs were emphysematous. Their posterior and inferior parts were moderately injected; their upper and anterior portions were pale. The pulmonary arteries, to their smallest branches, contained air-bubbles. The abdominal organs were normal. None of the blood vessels were observed to contain air. The brain was rather paler and more moist than usual; otherwise it was normal.

DR. L. R. STONE reported a case of

OSTEO-MALACIA¹

with autopsy.

DR. WEBBER said that in cases of locomotor ataxia the bones often become changed, the earthy salts disappearing, and fractures occur very easily; erosion of the joints is also not uncommon. He regretted that no examination had been made of the spinal cord, as it might have thrown some light on the localization of a trophic centre for bone. In some cases Charcot has shown that probably such a centre exists in the gray matter of the anterior cornua. The difficulty which the patient experienced in walking, even before the first fracture, might be an additional reason for suspecting ataxia.

DR. MINOT thought it remarkable that while observation showed that the cells of the anterior cornua were the seat of the trophic nervous system, yet destruction of those cells is not always followed immediately by muscular atrophy. In infantile paralysis the

¹ Vide page 220 of this number of the JOURNAL.

wasting is apparently only the consequence of the paralysis, and not primitive. The loss of electric (faradaic) contractility is also immediate in that disease, whereas in progressive muscular atrophy (apparently from the same lesion) the reaction persists as long as any considerable number of muscular fibres remain.

DR. WEBBER said that a case has been lately reported where the skin of the body above the umbilicus, including the arms and hands, was covered with an eruption which left scars behind it. After death the corresponding part of the cord was found to be diseased. In infantile paralysis a large number of nerve cells are suddenly destroyed, and all muscles supplied from them degenerate *en masse*, but in progressive muscular atrophy one cell after another changes, but the electrical reaction remains for some time, and the muscular fibres degenerate slowly; so many healthy fibres remain that their reaction obscures the reaction of the few diseased fibres. In infantile paralysis we often have a change of nutrition in the bones which would suggest a trophic centre in the cord.

DR. JOHNSON mentioned the case of a patient who was brought to the Massachusetts General Hospital with a fracture of the femur in the lower third. A diagnosis of locomotor ataxia was also made. The bone healed with a very large callus, but in good position. The patient was discharged from the hospital wearing a stiff bandage, but on taking this off, and walking about, the leg was again fractured, simply from the weight of the patient. In this case there had also been some previous trouble with the stomach and bladder.

DR. WEBBER said that in a majority of the cases of locomotor ataxia with gastric crises there was also some joint or bone affection.

DR. L. R. STONE then reported a case of

SUPPRESSION OF URINE,

with autopsy.

DR. MINOT called attention to the absence of delirium and coma in this case, in which the patient had passed nearly a week without urinating. There must have been some elimination of urea through the skin and lungs (as shown by the odor of the breath), and from the stomach by vomiting, which prolonged life. In these cases the line of elimination must be by some other channel than the kidneys, as these are blocked. He had found the use of pilocarpine of great benefit, given in quarter-grain doses by the mouth, or, in emergencies, subcutaneously. He had also used the drug in cedema of the lung in cardiac disease, in puerperal cases, and scarlet fever, with small elimination of urine, and had found it very reliable in its action, and generally giving great relief to the patient. The continued use of the drug is depressing, and it should be always given with care. A case was mentioned where there were severe uræmic convulsions, which ceased after the administration of pilocarpine, but the drug was continued, and the patient died.

DR. WEBBER said that in one case treated at the hospital the pilocarpine acted only slightly, but as the patient's skin was dry and harsh he was rubbed with oil, after which the pilocarpine given again seemed to bring on more profuse sweating.

DR. BUCKINGHAM spoke of his failure to get good results from the fluid extract of jaborandi, and Drs. MINOT and WEBBER reported the same difficulty.

DR. REYNOLDS had seen good results from the use

of one fortieth to one twentieth of a grain of pilocarpine given to children of nine years, every two hours, without any bad effect.

Recent Literature.

The Microscope and its Revelations. By WILLIAM B. CARPENTER, C. B., M. D., LL. D., F. R. S., etc. Sixth edition. Two volumes. New York: William Wood and Company. 1883.

The English edition of 1881 of this well known work has been reprinted to form the two volumes, for April and May respectively, of Wood's Library of Standard Authors. The American republication is in appearance far inferior to the original. Not only is the print very fatiguing to the eyes, so closely are the lines crowded together, but also the illustrations have lost nearly all their merits, so coarsely are they reproduced. Apparently every possible economy in the manufacture was utilized in order to diminish the cost of the volumes. The consequence has been so great an inferiority in execution compared with the English edition, that every one whose means permit will certainly prefer the original.

Carpenter's *Microscope* is a work for amateurs, and has long been, and is likely to continue an invaluable assistance to all who employ the instrument for their recreation.

The field it covers is so vast that of no portion is a thorough treatment possible, unless all proportion of parts be sacrificed. This necessity renders the work less useful to the professional scientist, who naturally soon gets beyond what is to be found in Carpenter concerning his special subject. To the amateur no such objections occur, for he finds here descriptions of all the acknowledged favorites of microscopists — flies' feet, sponge spicules, amœbas, vegetable spores, diatoms, etc. These descriptions are clear, and well explain to the amateur the meaning of what he may observe.

It is true that the author does not exhibit a sufficient familiarity with recent scientific literature. In many instances he fails to record established knowledge, and therefore, when writing upon subjects beyond his own observation, he is not infrequently inaccurate, or adheres to views and interpretations now set aside. Thus he again presents Balbiani's unscientific and obsolete notions about the sexual reproduction of the infusoria; the chapter on the sponges is very defective, for no mention is made of the most important researches of all, those of F. E. Schulze, nor are his results noticed, although they are the basis of our knowledge; indeed, the chapter on sponges is so replete with errors that it is a serious blemish; the organ of hearing described in the antennæ of insects is known not to be auditory but olfactory in function. We will not pursue further this ungrateful enumeration of faults.

The long introduction, devoted to descriptions of the complicated English machines known as the grand stands and all the "accessories" thereto, and the optical principles of the microscope, takes up more space than commends itself to our judgment. The account of the homogeneous immersion objectives and the discussion of the angle of aperture will interest and enlighten many readers.

To conclude, this work, despite obvious defects, still remains the best authority for the amateur microscopist.

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 6, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft or registered letter.

HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

MEDICAL MEN AND THE "CLASSICAL FETICH."

It is now two months since Mr. Charles Francis Adams, Jr., disturbed the dignified complacency of the Commencement season by a vigorous onslaught on the prevalent system of collegiate education. Our readers will remember the heavy arraignment he brought against the "fetich" of classicism as not only useless in a negative way as a preparation for the toil and sweat of this working-day world; but as positively injurious, on the one hand by taking the place of what might have been useful studies, or on the other by encouraging superficial and shiftless methods of thinking, inevitable from the imperfect way in which at the best the Greek language is now taught.

Immediately following this overt revolt against the supremacy of classical studies came a rattling fusillade from the small arms of the daily press, mostly, as was to be expected, on the side of the new departure. Later we have heard the heavier ordnance of the periodical magazines, notably the *Popular Science Monthly* and *Harper's Magazine* in their current issues. The attack of Mr. Adams is but a single movement in a conflict which has been long and severe, and will doubtless continue so long as there are boys (and girls) to be educated. But now that there is a temporary lull, while the smoke of the last engagement is rising, it is perhaps the duty of the medical journalist to step upon the field and see who is wounded.

To the physician it is certainly a question of vital importance, what form of mental training affords the best preparation for the study and practice of what has been called the gravest of the professions. Let us say at the outset that with the problem whether the traditional curriculum of academic training in most American colleges is the one on the whole better adapted than any other one system for affording the various professions the most useful common stock of mental nourishment, we have at present no concern, though it is in itself an important question. If doctors, lawyers, clergymen, artists must all have their early intellectual processes cast in the same mould, it is indeed a vital point that that mould be so formed as to distort and cramp the fewest minds possible. But, with the rapid extension of the elective system in our leading colleges, approximating that ideal condition in which each person may be given such individual train-

ing as is best adapted to his peculiar requirements, the question arises, What studies are best fitted to develop those qualities of mind essential to success in medicine? Or, as more directly suggested by Mr. Adams' oration, What, if any, is the value of classical training to the scientific man?

Experimental scientific pursuits are generally considered to imply a materialistic tendency of thought and belief. And yet it is to be said that Mr. Adams' point of view is more distinctively materialistic than any which the purely scientific man occupies. The railroad interest, in which Mr. Adams is engaged, might be taken as almost the type of materialism. In its broadest aspects it has to do only with the production of wealth, its highest studies are the future course of population and production, while its ordinary occupations are with questions of road-construction, transportation, and the management of machinery, both iron and human.

It need not be said that this is in no way to the discredit of the railroad business. It simply stands as the representative of nineteenth century money-getting. Now scientific research, especially such as is involved in the profession of medicine, is of a different nature. The student is constantly brought face to face with "ultimate facts," where reason and investigation are baffled. The origin of disease, the essential nature of pathological processes all lie beyond the reach of scalpel or lens. The practitioner in his daily duties is brought into contact with much besides purely material phenomena. He sees that psychical influences are often stronger than physical ones. He feels that his organs of sense cannot grasp the essence of life either at its inception or its dissolution. He is obliged to deal with the minds of patients as well as with the corporeal ills, and his mind needs to be as well furnished and trained as those he would influence. It may be said, then, that the training of the special senses, important as that is, is by no means all that the medical man requires. The inductive method necessitates close thinking, and that presupposes judicial qualities and a logical mind. To say nothing of the satisfaction which every one must feel in mental power, *per se*, and independently of his daily vocation, it is also true that the broader a man, the more of a doctor is he. On this point, Mr. Adams himself says:—

"And here let me once for all say that I am no believer in that narrow, scientific, and technological training which now and again we hear extolled. A practical, and too often a mere vulgar, money-making utility seems to be its natural outcome. On the contrary, the whole experience and observation of my life lead me to look with greater admiration, and an envy ever increasing, on the broadened culture which is the true end and aim of the university. On this point I cannot be too explicit, for I should be sorry indeed if anything I might say were construed into an argument against the most liberal education. There is a considerable period in every man's life when the best thing he can do is to let his mind soak and tan in the vats of literature. The atmosphere of a university is breathed into the student's system—it enters by the

very pores. I would not, therefore, narrow the basis; on the contrary, I would broaden it."

Some sort of a preliminary training, then, all will agree to be highly essential to one who is to undertake the study of medicine. Few things are more unsatisfactory than to see boys flocking to the large medical centres, when barely out from the common schools, unfit by their immaturity both of years and of mental growth for intelligent medical study.

"By their fruits ye shall know them," is an old maxim, and doubtless it is fair to apply it to this question of the results of classical training on the present generation of physicians. In looking back over the roll of names that have graced the medical profession in New England and the country at large for the last century, it is impossible to forget that the great majority were men who were educated in the old-fashioned college curriculum. Yet this only proves that such men were better fitted for their life work than those of their companions who had received no preliminary training. It reveals nothing as to what these same men would have accomplished if they had substituted French and German for Latin and Greek in their preparatory course. Undoubtedly there is truth in what Professor Youmans says, that "most men who have invested in classical education and find that they have been sold are anything but eager to acknowledge it," so that in looking back over his own intellectual history it is necessary for each one to guard against this danger of prejudice in favor of what he himself has. Few men in active practice, we apprehend, make any direct use of their classical attainments. An occasional help in the immediate understanding of some of the new terms that are multiplying in medical nomenclature is an advantage which is a poor substitute for facility at reading or speaking those languages in which so much of the professional progress of the present day is communicated. For the direct use of the physician Greek has little to claim. As a working tool it is infinitely less effective than German. Yet each must be his own judge as to how far his mental status has been improved by once having had that training. Dumb-bells and Indian clubs are less useful than shovels and picks, intrinsically, as tools for the performance of actual work, but sometimes their intelligent use makes a more perfect body, a frame more firmly knit, and capable of greater endurance than is that of the laborer. That German possesses any advantage over Greek for the purposes of an intellectual dumb-bell may well be doubted. As studied from a grammar, indeed, as studied under any circumstances except in the land where it is vernacular, it is not likely to be learned more thoroughly than any other exotic language, whether modern or classical. No American college student ever gains a thorough, that is, a speaking acquaintance with any foreign language. Its advantage over the Greek is certainly, then, not as a mental stimulant, but simply as a tool, and, considering the bondage to the lexicon of those who have studied it only in American colleges, not a very sharp tool at that.

It is interesting to see how highly classical studies have been prized by some of the most zealous devotees of science. James Mill, who had the most punctilious ideas of education, so that he allowed no one but himself to instruct his son, and presumably afforded just what he thought the most nutritious mental pabulum, included the classics as an important part of the son's training. And the illustrious John Stuart Mill himself testified in his old age to the value of his classical drill. Again, the great modern apostle of materialistic science, Professor Huxley, has sent his eldest son to Oxford, where the young man has just graduated with the highest honors which that university can bestow for classical learning.

Yet in spite of shining examples like these and others that might be cited, it can hardly be denied, we think, that classical study occupies a much less prominent place in the preliminary education of medical men than it formerly did.

The Faculty of the Harvard Medical School advise "undergraduates intending to study medicine to pay special attention to the study of natural history, chemistry, physics, and the French and German languages while in college."

The preliminary requirements for admission to the school are facility in the correct use of the English language, the ability to translate easy Latin prose, a knowledge of physics, and an acquaintance with one of the following subjects as the student may elect: French, German, the elements of algebra or of plane geometry, botany. The compulsory requirement of a moderate knowledge of Latin for those students who have not had a collegiate education is significant as showing the opinion of the Faculty regarding the advantage of that language. Indeed, few will deny that for its intrinsic uses, including the basis of nomenclature in every branch of science, as well as for its collateral benefit in forming a common foundation for the understanding of most modern languages, it is far more valuable than Greek.

The "experimental method," with the changes that it has introduced into the most advanced system of medical instruction, is undoubtedly working backward as an influence upon academic education.

In Dr. Whittier's paper on Recent Changes in Methods of Medical Instruction, read at the last session of the Massachusetts Medical Society, it was said incidentally that it was desired by some of the Medical Faculty, as soon as possible, to include descriptive anatomy and general chemistry among the subjects for preliminary study, so that the time of the medical course could be given more exclusively to laboratory and clinical work. Of course the tendency of this is to abridge the time given to classical study. Indeed, we think observation will bear out the statement that for the last decade few who intended making medicine their profession have devoted much more time to Greek than the minimum required by their college. It is to meet this desire on the part of its students that the elective system at Harvard has been established, and its constant and rapid growth in the direction of natural science and allied branches indicates

the strength of that desire. A glance through our medical catalogues shows the increasing number of degrees other than A. B. held by the students.

The Lawrence, Sheffield, Chandler, Massachusetts Technological, and other scientific schools undoubtedly attract from the academical departments of their respective universities a certain proportion of the young men contemplating medical study. The new Harvard Medical School building is a neighbor of the Massachusetts Institute of Technology, and the hospitable attitude shown our State Medical Society at its last annual meeting by that institution is an indication, if we mistake not, that its officers desire a closer relationship with the medical profession, and hope to make their valuable school a feeder to it. While, then, we are far from admitting the truth of Mr. Adams' sweeping criticism on classical studies as useless to a practical scientific man, we can but confess, with a certain regret, that they are losing the place which they formerly held as the only orthodox gateway to our profession. If the change is to justify itself it must be by imparting a new impetus to those experimental methods in which the future hope of medicine lies.

THE STUDY OF MEDICINE IN ITALY.

THE period of study necessary for the acquisition of a thorough medical education and the proper standard to impose for conferring a degree are subjects which have been so much discussed of late years, especially in our eastern cities, that the arrangements in vogue in these regards in other countries have an unusual interest. From this point of view we took pleasure in reading an account of medical instruction in Italy, by Prof. J. Bizzozero, of Turin,¹ and we may confess our pleasure was mingled with surprise.

We take it that if the majority of our English-speaking medical contemporaries ever associate the name of Italy at all with scientific or medical activity their minds revert to Galileo or to the palmy days of the University of Padua, when the studious and gentle youth of England, as of other northern countries, who were young with Bacon, and Shakespeare, and Harvey, made that long and expensive journey at far greater risk and outlay than allows us to safely reach Paris or Vienna to pursue those advanced studies or to obtain that finish which could not be followed or gained at home, or, it may be, merely in order to come back and say they had been there. By indulging these associations it is very possible that we do not exaggerate the respect due to the Padua and Bologna of two and three centuries ago, but by taking pains to inform ourselves we should certainly find that we had been neglecting to appreciate scientific and medical Italy of our own time.

The Italian universities are now governed by a law passed in the Kingdom of Sardinia in 1859, which, with some modifications, is now applied to the whole peninsula, and they are all under the control of the state. A student wishing to matriculate at one of the med-

ical schools must have a diploma either as bachelor of letters or of science, and, in addition, a knowledge of one of the modern languages, generally either French or German, and of drawing. He pays 40 francs to the state on matriculating, and a further sum of 660 francs during the different years of his course; at examination he pays 100 francs, and 60 francs for the diploma. In all 860 francs are paid by the student to the state before receiving a degree.

The courses of study cover six years, and are detailed under eighteen heads, namely: (1) general organic and inorganic chemistry; (2) botany; (3) zoology, comparative anatomy, and physiology; (4) experimental physics; (5) human normal anatomy; (6) human physiology; (7) general pathology; (8) pathological anatomy; (9) *materia medica* and experimental pharmacology; (10) special medical pathology; (11) special surgical pathology; (12) clinical medicine; (13) clinical surgery and operative medicine; (14) ophthalmology; (15) pathological and clinical dermatology; (16) obstetrics; (17) state medicine and public hygiene; (18) mental diseases. All of these courses are annual except pathological anatomy, to which two years are given, and human anatomy and the general clinical branches, each of which require three years.

In the University of Turin, one of the larger and more vigorous, these studies are divided as follows: first year, physics, botany, and zoology the first half, or four months; comparative anatomy and physiology the second half. Second year, chemistry (organic and inorganic), human anatomy, and human physiology. Third year, human anatomy completed, human physiology, general pathology. Fourth year, *materia medica* and experimental pharmacology, special medical pathology, special surgical pathology, clinical symptomatology, clinical surgery, pathological anatomy. Fifth year, pathological anatomy, operative medicine, topographical anatomy, hygiene, ophthalmology, clinical medicine. Sixth year, legal medicine, clinical medicine, operative clinical surgery, obstetrics and clinical obstetrics, dermatology and syphilology, theoretical and clinical, mental diseases, reviews of previous work.

In this schedule, which is not compulsory, the first three years are occupied especially by the purely scientific part of the studies, and the daily routine comprises few courses, whilst the last three years are devoted to the practical part of medicine.

In addition to the regular courses of instruction there are at the largest schools a very considerable number and variety of semi-official courses — *cours libres* — given by the extraordinary professors, and of private or extra-mural courses given by *privati docti*. Of these teachers the former receive a fixed salary, and the latter a certain sum for each student taking their course.

The official professors are of two grades, ordinary and extraordinary, the former having the advantage of receiving larger salaries and being permanent appointments, whilst the latter are appointed annually. The regular courses are given, as far as possible, by the ordinary professors, and their mode of appoint-

¹ Archives Italiennes de Biologie, May, 1883.

ment combines the advantages of the *concours* and a consideration of general fitness. The minister of public instruction may appoint directly, but this power is very rarely used. The usual procedure is for the minister, upon request of a school having a vacancy in its faculty, to name a jury or commission, only one member of which can be taken from the interested school, of from five to nine members, the majority of whom must be composed of ordinary professors teaching the same branch as that under consideration. This commission examines the titles of the applicants, their published works, positions held, courses given, etc., etc., and separates those who are eligible from the ineligible, placing the names of the former on a list in order of merit, the first being generally appointed by the minister. In case the claims of no applicant entitle him to be declared eligible the selection is made by *concours*, and the successful concurrent is appointed simply professor extraordinary. This system for the selection of professors is said to have given very good results in general in Italy, and to it particularly the scientific revival observable at the universities should be attributed.

The time of study — six years — required in Italy before taking a degree in medicine is two years longer than in Germany, and one year longer than in Austria or Russia, the same as that in Holland, and one year less than that in Sweden. In the Italian schools a large proportion of the time is devoted to the natural sciences and to anatomy, human and comparative.

There are twenty medical schools in Italy at the present time. Those of Bologna with 306 students, Naples 1389, Padua 278, Palermo 156, Pavia 316, Rome 219, and Turin 534, are official, complete, and of the first class; those of Cagliari 31, Catania 47, Genoa 201, Messina 38, Modena 95, Parma 100, Sassari 39, are complete and official, but are rated as of the second class; those of Pisa 147, Sienna and Florence 138, are official but incomplete, the two first giving only the first four courses, and the last only the last two courses; those of Perugia 31 students, Camerino 48, and Ferrara 11, are free and incomplete schools, — Perugia giving only the first four years, Camerino and Ferrara only the first two years.

The revival in medical studies in Italy has been brought about within the last twenty-five years, and has undoubtedly made very gratifying progress. Without allowing one's self to be deceived by prospectuses, with which sort of parade we are quite familiar, or supposing that mere length of residence is in itself an education, it is evident that medical education at the first class Italian universities is to-day both liberal and serious. And Professor Bizzozero makes it apparent that there is a spirit abroad which will not rest contented till even more is accomplished. More liberal government appropriations and more general hospital and laboratory facilities are still demanded and expected.

— J. B. Lippincott & Co. announce that the third volume of Agnew's Surgery, which brings this great work to a close, will be ready on September 1st.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

THE American Public Health Association will hold its eleventh annual session at Detroit, Michigan, commencing Tuesday, November 13th, and ending Friday, November 16th.

The following subjects have been chosen for special consideration at the approaching meeting, as we learn from the Secretary of the Executive Committee:—

(1.) *Malaria*. Its ætiology and the methods for its prevention in localities or in persons; its American history; its specific particles; its origin; the conditions of its pervasion; its laws of extension, etc.

(2.) *Foods*. Their adulterations; healthy or deleterious modes of preservation and the function of legislation in regard to them. Ascertained facts as to adulterations in this country. Facts as to canned goods, condensed milk, artificial butter and cheese, prepared meats, etc.

(3.) *Vital Statistics*. Methods and results; defects apparent. How far foreign modes of tabulation are to be followed. Systems of collection and classification. Race vitality and the care of population as indicated by statistics.

(4.) *The Control and Removal of all Decomposable Material from Households*. The mechanical laws, constructions, and appliances relative thereto. The construction of all inside pipes and their connections, their traps and siphonage, flushing, ventilation. How they shall be connected with out-door receptacles and yet be free from ill effect.

The Executive Committee desires to avoid general dissertations on these subjects, and to secure facts and opinions as to practical methods of dealing with the interest of public health. Reasons for views entertained and results of experience as to preventive and restrictive measures are especially sought.

Papers of merit on other topics will not be rejected, but it is desired to concentrate attention, as far as possible, upon the above subjects. Methods and systems of physical education, drill, etc., suitable for the school-room, will also be discussed.

Reports are expected from special committees on compulsory vaccination, the management of epidemics, and on diseases of animals, and these committees will be glad to receive communications bearing on these subjects.

Gentlemen proposing to present papers are requested to notify the Secretary, giving titles of papers, and a statement of the time required for reading, with a synopsis of such papers *must* be in the hands of the Secretary by October 15th.

— Mr. W. F. Phillips, in the *British Medical Journal* for 14th July, recommends belladonna in the treatment of hay fever or summer catarrh, and records a case in which it proved very successful. He used the *Succus belladonnæ*, and gave at first one minim every hour, and afterwards one and one fourth minim every hour till relief was obtained.

MEDICAL NOTES.

— A member of the New England Divorce Reform League, Mr. S. R. Dyke, states that over six thousand women die yearly in the United States from attempts to destroy unborn children.

— Oil of wintergreen (salicylate of methyl) diluted with an equal quantity of olive oil or soap liniment, applied externally to the joints affected by acute rheumatism, gives prompt relief, and, from its pleasant odor, is very agreeable to use. — *The Quarterly Therapeutic Review.*

— "Physio-medicalism" is a sect which complains that it has received no representation in the Missouri Board of Health. If such bodies are to be organized on a sectarian basis, we fail to see why the physio-medicalists have not a good case. Their organ, published in Indianapolis, calls upon the faithful to organize, "to secure our rights, maintain our principles, protect ourselves, become a power in the land, and establish scientific medicine."

— Mr. Fitzpatrick gives in the *Lancet* his recent experiences in the treatment of hordeolum, or the common sty, during the time he was in Egypt. The plan of treatment adopted is to dispense with hot fomentations, etc., and to apply locally tincture of iodine to the lids, care being taken to keep them apart until dry. A few applications in the twenty-four hours is often sufficient to arrest the development of the sty.

— At the last annual meeting of the American Institute of Homœopathy, according to the report given in the *New England Medical Gazette*, a paper was read on the Solubility of Glass, in which the writer "showed that in the process of grinding a more or less appreciable quantity of the material of the mortar became detached and incorporated with the trituration." Another writer of "great scientific ability" declared that "there is absolutely not such a thing as perfectly pure sugar of milk to be obtained in the market, and consequently all triturations of medicine must contain more or less of admixtures, which might have an antidotal effect upon the remedy which it was desirable to administer. He found that sugar of milk contained in varying proportions *silica, calcaria, phosphorus, iron, and magnesia*, enough in many cases to equal the fifth or sixth decimal trituration." The practical conclusion of this paper was, "*we should also see to it that the impurities do not preponderate over the drug in the medicines which we administer.*"

— A correspondent of the *New York Medical Journal*, writing from Vienna, says: "One only needs to be here a few days in order to become convinced of the truth of the reports which he has received at home in regard to the growing rapacity (to use a term not too strong) of the average Vienna assistant. The tendency to shorten the courses and increase the fees offers an alarming prospect for the student of the future. Unless I am greatly mistaken in regard to the expressions of dissatisfaction which I hear universally from Americans who have been long studying here, the time is coming when the increasing clinical facilities of our own larger medical centres, and the

greater courtesy, not to say conscientiousness, of our instructors, will render foreign medical study less fashionable than it used to be. Certainly the opportunities for post-graduate work in New York are not to be despised even now in comparison with those of Vienna."

Correspondence.

SURGICAL APPLIANCES FOR DISABLED SOLDIERS AND SAILORS.

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE, {
WASHINGTON, D. C., August 28, 1883. }

MR. EDITOR, — Congress having appropriated a small sum for furnishing special surgical appliances to those disabled in the military or naval service, your coöperation is respectfully invited in order that this relief may reach the class of persons intended to be benefited.

This office is desirous of obtaining authentic information regarding all existing cases of severe and unusual injuries. Should you have occasion to report such, it will be found useful to bear in mind the following points:—

(1.) As no money commutation is authorized only such cases need be presented as offer a fair prospect of being relieved by surgical or mechanical appliances.

(2.) Artificial limbs and apparatus for disabled limbs being otherwise provided for by law, the injuries here in view are almost exclusively those affecting the head, face, or trunk.

(3.) As trusses are furnished under special legislation, hernia, when not complicated with other injuries, is not to be understood as covered by this appropriation for *special* appliances.

(4.) As the appropriation is small, it is proper that it be expended only on the most meritorious cases. It is therefore not intended to furnish appliances which are ordinarily within the means of the individual, nor those that are of a character so perishable that it would be difficult to keep up the supply. Regard is to be had chiefly to the severity of the injury and the ability of the sufferer, unassisted, to procure relief.

Very respectfully, your obedient servant,

C. H. CRANE,
Surgeon-General U. S. Army.

"THE IMMEDIATE AND FORCIBLE REMOVAL OF THE PLACENTA AFTER ABORTIONS."

MR. EDITOR, — My attention has just been directed to a letter from Dr. Paul F. Mundé, contained in your issue of the 16th inst., in which he charges me with a willful misinterpretation of the word "forcible" used by him in his paper advocating "the immediate and forcible removal of the placenta after abortions." This is an imputation under which I cannot rest without a demur. I quoted his language correctly, and if I have failed to comprehend its import, I prefer the fault to be considered one of the head rather than of the heart.

If I understand him rightly, he advocates as a rule of practice, "the immediate and forcible removal of the placenta after abortions." This is certainly plain enough as a general proposition, capable of but a sin-

gle interpretation, and one to which I object as being' in my humble opinion, unsound in theory and unsafe in practice.

The *quality* of force to be employed in the manipulation, he informs us, should be "*well directed and controlled, intelligent force*;" that when he said "*force should be absolutely avoided*," he meant "brutal, ill-applied force or violence," and he seeks to strike a parallel between the force proper to use upon these occasions and that employed in extracting the foetal head by the obstetric forceps. There can be no two opinions upon the character of the force that should be used if employed at all.

Now, as to the *extent* or *degree* of force to be exercised, if I were to determine it from what I conceive to be the spirit and the letter of the general proposition above referred to, I would say that it should be sufficient to accomplish the desired object, be that amount great or small. When Dr. Mundé says: "If the placenta can be removed without undue violence, either by means of the fingers or some instrument, it should be at once removed," I take it that if necessary, that force may even amount to *violence* if that violence be not "*undue*."

I may not understand the English language well enough to catch his full meaning; until I do, the "*forcible, instrumental, IMMEDIATE delivery of the placenta after abortions, without undue violence, as a rule of practice*," will appear to me an unsolved conundrum.

Yours truly,

H. V. SWERINGEN.

197 WEST WAYNE STREET, FORT WAYNE, IND., }
August 28, 1883.

Miscellany.

TRICUSPID REGURGITATION.

In a clinical lecture, Dr. John S. Lynch, of Baltimore (*Maryland Medical Journal*, August 18th), describes a case of this rather rare malady occurring in an unmarried female, aged thirty-three, who had been suffering from shortness of breath for three years. Rheumatism and syphilis were denied, but the latter presumably falsely so. Extreme ascites, with probably an ovarian tumor in addition, cyanosis, and marked venous pulsation were present. The physical signs were thus described and commented upon:—

"Upon inspection and palpation we find that the apex reaches far around to the left, quite beyond the mammary line; the impulse of the heart is seen and felt over a wide area, and the chest wall is visibly lifted at each pulsation. This indicates enlargement, and particularly enlargement of the right ventricle. For as the apex is included in the left ventricle, and the heart rests upon the diaphragm by its right ventricle, enlargement of this ventricle will have the effect of pushing the apex to the left and upwards,—precisely the condition we have here. The ventricle is then certainly enlarged; but whether this enlargement is due to pure hypertrophy or to hypertrophy with dilatation or to dilatation alone is not so easy to determine, by any objective physical signs. On the left side of the heart we can readily determine the fact by noting the characteristics of the pulse. If with an enlarged area of dullness, and a heaving, diffused impulse, we have a full, strong, and bounding pulse, then we know there is hypertrophy alone. But if with these the pulse is

small, feeble, and quick, and out of proportion to the apparently vigorous and active heart, then we know there is dilatation. In case of enlargement of the right ventricle, however, this sign is denied us. We cannot "feel the pulse" here. Can we, then, reach no conclusion in the matter? Is there no sign that will throw any light upon this question? Yes, we can inquire into the state of the pulmonary circulation, which will suffer the same alterations in right hypertrophy or dilatation that the systemic circulation does from alterations in the heart upon the left side. But here again we are met with another difficulty. Too much blood in the lung, or I should say too great blood pressure in the lung, gives rise to the same symptom that is present in too little blood in the lung. That is a subjective sensation of dyspnoea. The person feels that he cannot get "breath enough," and he will also suffer more or less in either case from a sensation of constriction in the chest. But there is this difference in the two conditions which in doubtful cases may be relied on to distinguish the one from the other. When there is too much blood in the lung the person will have, in addition to the subjective sensations I have described, a *cough*, which becomes more and more troublesome as the blood pressure increases, until finally stasis of the pulmonary circulation ensues with carbonic acid poisoning of the centres of sensation and consciousness, after which all cough ceases, because the person no longer feels or perceives the irritation which caused him to cough. When there is not enough blood in the lung this cough is not present; although the same result will be finally reached, namely, carbonic acid poisoning and coma, as in the other case. Here, then, we have a symptom by which we can arrive at a conclusion. If there is hypertrophy, pure and simple, of the right ventricle, the patient ought to have dyspnoea *with* a cough; if there is dilatation, and of course consequent weakening of the ventricular walls, there should be dyspnoea *without* cough. Upon inquiry she tells us she coughs only when she has a cold, and you will have noticed that she has not coughed once since she has been in the lecture-room."

The stethoscope revealed, continued the lecturer, "a faint, low-pitched, systolic murmur, whose point of greatest intensity is over the right edge of the sternum at the fourth intercostal space and over the fourth cartilage. It is so faint that it cannot be traced far in any direction from this point. But it cannot be heard at all over the apex of the heart, where we would hear a mitral murmur, nor over the mid-sternum at the third cartilage, where we would hear an aortic direct murmur, and hence cannot be produced by a lesion of either of these valves or orifices. The tricuspid regurgitant murmur is said to be generally accompanied by a mitral regurgitant one also, but in this case there does not seem to be any lesion of the mitral, or if there is, it is not accompanied by a murmur. You will remember, however, that absence of a murmur is not positive evidence of the non-existence of a valvular lesion, since the very lesion we are now discussing certainly exists sometimes—demonstrated by an unmistakable venous pulsation—without a corresponding murmur. Indeed, I have a lady now under observation for about ten years, who formerly had a strong mitral murmur which has now disappeared entirely, notwithstanding her heart trouble has become so bad that she has not been able to sleep for many months in the recumbent position, except when under the influ-

ence of morphia and digitalis. In the present case, while we have strong venous pulsation, apparent even from quite a distance, the murmur is very faint and low pitched. I beg leave to remind you, therefore, that the gravest valvular diseases are not always attended with the strongest murmurs. Nor do loud-pitched and hissing murmurs always indicate grave lesions."

THE TREATMENT AND CURABILITY OF CHRONIC UTERINE CATARRH.

At a meeting of the New York Academy of Medicine Dr. Paul F. Mundé read a paper on this subject, which is reported in the *American Journal of Obstetrics* for August. After alluding to the significance of the condition with reference to sterility, he says that in the nullipara it is often difficult to understand the reason for the sterility. In these cases the following condition of affairs was described: The narrow external os usually entails a retention of normal cervical discharge; this retention gradually produces dilatation of the cervical canal, and the accompanying retention causes hypersecretion until the cervix assumes a bulbous shape, and its cavity is filled with thick, viscid, discolored mucus. When the external os is dilated by the passage of the sound, and the cervix is compressed by the examining finger, mucus gushes out in a thick stream; the sound easily detects the presence of a large cavity within the narrow external os. This condition is not at all unfrequent, and is as unfailing a cause of sterility as it is curable by prompt and proper treatment.

Dr. Mundé then described briefly the plan of treatment which he had employed for several years, and which he had found to answer fairly well in the majority of his cases. He began by saying that it was utterly useless to expect to cure a chronic uterine catarrh by such mild remedies as the plain or even compound tincture of iodine, or solution of nitrate of silver, even one drachm to the ounce, or pure carbolic acid. You will certainly fail in chronic coporeal metritis, and in the cervical variety you will merely increase the discharge.

If the patient is a virgin or a nulliparous married woman it will generally be found necessary to enlarge the external os. This is essential for two reasons: first, to give vent to accumulated endocervical mucus; second, to allow the ready application of remedies. To accomplish the first, expose the cervix through Sims' speculum,—it can be imperfectly done through the ordinary cylindrical speculum,—and then with a Sims' uterine knife, or a simple bistoury or straight scissors, the anterior, posterior, and lateral lips are divided by incisions, about one fourth of an inch in depth, going completely through the mucous membrane, and making the os nearly or quite as large as the calibre of the cervical cavity. It is imperative to remove the four flaps of mucous membrane thus formed in order to prevent the speedy closure of the incisions. Seize each flap with a fine tenaculum, and trim it off with curved scissors, so as to leave a funnel-shaped external os. It is not necessary to perform this operation in every nullipara. The next step is to destroy as thoroughly as possible the cervical glands which furnish annoying mucous secretion. To do this effectively, once and for all, take a sharp curette with cutting edge (Sims' or Simon's), and scrape the whole

cervical canal up to the internal os until the creaking sound tells you that the sub-glandular base has been reached. Do not be afraid to do this thoroughly. When the whole of the canal feels smooth apply, on a cotton-wrapped applicator, or, better, a wooden or glass rod, pure nitric acid, being careful to protect the external surface of the cervix and also the vagina by packing cotton underneath. This application must be so thorough as to give the cervical canal a charred, yellow appearance, so that not even a drop of blood issues from it. In some instances he had applied the iodized phenol (equal parts) or saturated solution of chromic acid, but he preferred the nitric acid as more efficient and scarcely more painful. The operation should be performed at the residence of the patient, and the latter kept quietly in bed for a day or two at least. Three cases of cellulitis following this really trifling operation have induced him of late always to insist on this precaution.

While applications above the internal os are more liable to produce shock and peritonitis, those to the cervix are more frequently followed by inflammation of the pelvic cellular tissue. In spite of this danger the severe measure (sharp curetting and nitric acid) is by far the most advisable because it is the most effectual, and he had never as yet found it necessary to substitute the actual cautery so warmly recommended by Sims.

As for catarrh of the endometrium proper, he seldom used a sharp curette above the internal os except when it is for the purpose of removing vegetations or hypertrophied mucous membrane of unusual growth, or where the dull curette has not prevented a return of the disease.

An indispensable condition to the safe and complete application of caustics to the endometrium is the patulousness of the uterine canal, particularly of the internal os. Whether the application be made to the whole of the uterine canal or to the cervix alone it must be remembered that the more powerful the caustic the longer the time before the slough separates. That of nitric acid usually takes from five to seven days; iodized phenol or pure carbolic acid, three to four days; tincture of iodine, two days. Not until the slough has separated should a second application of a mild nature be made. It should be remembered, however, that so long as constant applications of caustic are made to a raw surface it cannot heal. Hence it is well, after a couple of weeks of steady treatment, to allow the patient a week's rest in order to give nature a chance to heal the wound. If she then fails we can begin again, and, perhaps, a third or a fourth time.

The cases he had found the most amenable to treatment and most favorable for a permanent cure were those in which the uterine catarrh is chiefly maintained by a narrow external os or internal os, or where a laceration of the cervix and a consequent hyperplasia of the follicles is present. The most obstinate are those cases of catarrhal endometritis and endocervicitis in which the external and internal orifices are anatomically normal, and no special hyperplasia of the os or mucous membrane can be detected. In these cases permanent relief seemed hopeless. The intelligent specialist and general practitioner need scarcely be told that accompanying anæmia must receive proper attention, and active hyperæmia of the sexual organs should be prevented by abstinence from sexual congress during the local treatment described.

TREATMENT OF WHOOPING-COUGH.

DR. ARCHAMBAULT (*Gaz. des Hôpit.*, No. 28, 1882, and *Progrès Méd.*, Nos. 48-52, 1882) recommends that children suffering from this disease should be kept indoors, and that special attention should be paid to keeping the temperature of the rooms they occupy uniform. He states that by means of such precautions

"it is almost certain that such lung complications as capillary bronchitis and broncho-pneumonia may be prevented." In support of his advice he points to the fact that summer attacks of the disease are always milder than those occurring in winter. The drug he recommends is sulphate of atropine, 1-1000, one drop thrice daily for children a year old, two drops for two-year old children, and so on.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 25, 1883.

Deaths reported 3143 (no report from New Orleans): under five years of age, 1521: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 1168, diarrhoeal diseases 755, consumption 390, lung diseases 128, diphtheria and croup 106, typhoid fever 103, scarlet fever 66, malarial fevers 41, whooping-cough 34, measles 22, cerebro-spinal meningitis 20, puerperal fever 14, erysipelas four, small-pox three. From scarlet fever, New York 11, Chicago 10, Baltimore nine, Philadelphia eight, St. Louis seven, Brooklyn and Buffalo five each, Lowell three, District of Columbia two, Boston, Cincinnati, Pittsburg, Milwaukee, Cambridge, and Lawrence one each. From malarial fevers, St. Louis 14, New York 11, Brooklyn seven, Baltimore four, Buffalo two, Chicago, Charleston, and Salem one each. From whooping-cough, New York 11, Baltimore five, Chicago four, Philadelphia, Brooklyn, District of Columbia, and Pittsburg three each, St. Louis and Cincinnati one each. From measles, New York 11, Baltimore three, Philadelphia two, Brooklyn, Chicago, Boston, St. Louis, Cincinnati, and District of Columbia one each. From cerebro-spinal meningitis, Buffalo six, Chicago four, Philadelphia two, New York, St. Louis, Providence, Charleston, Lynn, Holyoke, Brockton,

and Peabody one each. From puerperal fever, New York three, Brooklyn and Boston two each, Philadelphia, Buffalo, Milwaukee, Providence, Charleston, Peabody, and Westfield one each. From erysipelas, New York, Baltimore, Providence, and Lynn one each. From small-pox, St. Louis two, Philadelphia one.

Six cases of small-pox were reported in St. Louis; diphtheria 23, typhoid fever 21, scarlet fever 14, and measles one in Boston; scarlet fever 12, and diphtheria two in Milwaukee.

In 37 cities and towns of Massachusetts, with an estimated population of 1,108,343 (estimated population of the State 1,922,530), the total death-rate for the week was 25.57 against 25.72 and 26.53 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending August 11th the death-rate was 18.4. Deaths reported 3039: diarrhoea 254, acute diseases of the respiratory organs (London) 177, measles 108, scarlet fever 106, whooping-cough 50, fever 46, diphtheria 29, small-pox (London, Birmingham, Leeds, and Newcastle two each) eight. The death-rates ranged from 11 in Halifax to 26.2 in Liverpool; Bradford 14; Bristol 15; London 17.3; Leeds 17.5; Nottingham 18.1; Birmingham 18.2; Brigh-

ton 18.8; Leicester 19.3; Sunderland 21.1; Newcastle-on-Tyne, 22.7; Sheffield 23.1; Manchester 23.8. In Edinburgh 15.5; Glasgow 24.8; Dublin 20.9.

For the week ending August 4th, in 167 German cities and towns, with an estimated population of 8,553,274, the death-rate was 26.7. Deaths reported 4397; under five years of age, 2562; diarrhoeal diseases 436, consumption 498, lung diseases 272, diphtheria and croup 129, measles and r6theln 70, scarlet fever 59, typhoid fever 59, whooping-cough 58, puerperal fever 11, small-pox (Ratibor one) one, typhus fever (Glauchau one) one. The death-rates ranged from 40.3 in Munich to 11 in Gladbach; K6nigsberg 27.3; Breslau 34.4; Dresden 27; Berlin

32.8; Leipzig 24.7; Hamburg 25.8; Cologne 26.2; Frankfort a. M. 18.1; Metz 16.4.

For the week ending August 11th, in the Swiss towns, there were 26 deaths from diarrhoeal diseases, consumption 18, lung diseases nine, typhoid fever eight, whooping-cough five, measles two, scarlet fever two, diphtheria and croup two, erysipelas one. The death-rates were at Geneva 11.3, Zurich 19.3, Basle 20.6; Berne 33.9.

The meteorological record for the week ending August 25th in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

Date.	Barom-eter.	Thermom-eter.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING WEEK ENDING SEPTEMBER 1, 1883.

T. C. WALTON, surgeon, detached from the Powhatan, and ordered to the Naval Academy.

SIMON, W. J., surgeon, detached from the U. S. S. Constellation, and, after completing temporary duty as member of a board at Annapolis, Md., to be placed on waiting orders.

McCLURG, W. A., passed assistant surgeon, detached from the U. S. S. Dale and ordered to the Naval Academy.

DIEHL, OLIVER, assistant surgeon, detached from the U. S. S. Constellation and ordered to the Naval Academy.

JONES, M. D., passed assistant surgeon, ordered to temporary duty at the Naval Hospital, Washington, D. C.

GYNÆCOLOGICAL SOCIETY OF BOSTON. — The next regular meeting will be held on the second Thursday of September, at the Medical Library Rooms, at four o'clock P. M. S. N. Nelson, M. D., of Cambridge, will read a paper upon The Uses of the Obstetric Forceps. Lunch served at close of session.

HENRY M. FIELD, M. D., Secretary.

BOOKS AND PAMPHLETS RECEIVED. — Training Schools for Nurses. With Notes on Twenty-Two Schools. By W. G. Thompson, M. D. New York: G. P. Putnam's Sons. 1883.

Hysterical Convulsions and Hemi-Anæsthesia in an Adult Male. Cure by Metallo-Therapy (Gold) By E. B. C. Seguin, M. D. (Reprint.) 1883.

Fifteenth Annual Report of the President of the Inebriates' Home, Fort Hamilton, N. Y., for the Year 1882. Brooklyn. 1883.

A Contribution to the Study of Neglected Lacerations of the Cervix Uteri and Perinæum. By Thomas A. Ashby, M. D., Professor of Obstetrics, Woman's Medical College of Baltimore, etc. Read before the Clinical Society of Maryland, May 4, 1883.

A Case of Pulsating Exophthalmus. Ligation of the Left Common Carotid. Death. By David Coggin, M. D. Salem, Mass. (Reprint.)

Second Annual Report of the State Board of Health of the State of New Hampshire for the Fiscal Year ending April 30, 1882.

The Essentials of Pathology. By D. Tod Gilliam, M. D., Professor of Pathology, Starling Medical College, etc. Philadelphia: P. Blakiston, Son & Co. 1883.

Report on Diseases of Women, from the First Congressional District. By R. J. Nunn, M. D. Savannah, Ga. (Reprint.) 1883.

Fourth Annual Announcement of the College of Physicians and Surgeons, Boston. Session of 1883-1884.

The Management of Abortion. By Walter Coles, M. D. (Reprint.)

McGill University, Montreal. Fifty-Seventh Annual Announcement of the Faculty of Medicine. Session of 1883-1884. Montreal. 1883.

Sanitary and Statistical Report of the Surgeon-General of the Navy for the Year 1881. Washington. 1883.

Original Articles

THE SCHOOL OF VETERINARY MEDICINE OF HARVARD UNIVERSITY.

BY C. F. WITHINGTON, M. D.

DURING the present month this new department of the university opens its doors for the first time to students. The successful inception of an undertaking of this importance simultaneously with the inauguration of the new and commodious building devoted to the uses of the Medical School, is indicative of the strong support which institutions of sound learning can rely upon in their endeavors to furnish the most advanced and thorough instruction in any branch of knowledge. A full description of the new Medical School building has been published in this Journal, and it is thought that it may be of interest to men who are engaged in a profession which has so much in common with veterinary science, to hear what is to be done in that allied department. The present development of veterinary medicine by men of culture and long training in the principles and practice of their art, is perhaps only one phase of the general advance in scientific methods which late years have witnessed, but it is certainly among the most striking, by reason of the contrast which it presents to the low state of the profession as represented in the average "horse-doctor" of the previous generation. There can be no doubt that the intelligent diagnosis and skillful treatment of disease in animals which can give no aid by subjective symptoms, furnishes a broad field to ability of the very highest order.

An ordinary English education, such as is gained in the common schools, is for the present all that is required in the way of preliminary education from candidates for this school, though it is recommended that candidates present themselves for an examination equivalent to that required of medical matriculants. The course of study extends over three full years, with examinations annually on certain specified subjects—arranged in a logical gradation. On looking over these subjects one sees that they are almost identical with those of the corresponding years respectively at the Medical School. For instance, the first year is devoted to anatomy, physiology, general chemistry, and botany, the latter subject being a requirement as yet in advance of the Medical School. The studies of the second year are practical anatomy, medical chemistry, materia medica, pathological anatomy, surgical pathology, clinical medicine, and clinical surgery; and of the third year, therapeutics, obstetrics, theory and practice of veterinary medicine, clinical medicine, veterinary surgery, clinical surgery, ophthalmology, parasites and parasitic diseases.

The school proper is located at the Bussey Farm in West Roxbury, where the most of the didactic lectures, recitations, and laboratory work will be conducted. The laboratory practice covers dissection, chemistry, histology, and botanical analysis, all under the supervision of competent instructors. Many of the professors are the same men who teach analogous subjects in the Medical School, as for instance the instructors in physiology, pathology, therapeutics, chemistry, and embryology. The more distinctively veterinary portion of the instruction is for the present entirely in the hands of Dr. Charles F. Lyman, F. R. C. V. S., who holds the

chair of veterinary medicine, and of Dr. Harrison, V. S., who lectures on comparative anatomy.

The custom of employing medical men to give the instruction on general medical subjects is one which obtains in most veterinary schools, and the advantages of this method would seem evident, despite the fact that it has been made the subject of adverse criticism in some quarters. Chemistry is chemistry, for whatever purpose it is learned, and the better the instruction offered the more to the benefit of the student. After a year or two, when the classes have reached the higher grades of the course, other veterinarians will be added to the corps of instructors as may be found necessary.

For the clinical portion of the instruction the school depends chiefly upon the new veterinary hospital which has been recently completed in this city, and which is without doubt the largest and most perfectly appointed institution of its kind in any English-speaking country, if not in the world. It should be understood that the hospital is not a part of the school, having the same relation to it that the general hospitals of Boston do to the Medical School. By an arrangement between the two institutions the surgeons are able to make the opportunities afforded by the hospital available for the instruction of the students. To the courtesy of Dr. Lyman and his assistant, Dr. Harrison, the writer is indebted for being kindly shown the resources of the hospital and for many of the facts which he is able to present in this article.

The structure, situated on Village Street in this city, opposite the stables of the Adams Express Company, is of brick, containing three stories above the basement. At the front are two doors, one for the admission of patients, and the other for the use of attendants and visitors. At the left as one enters are the offices of the surgeon and the assistant surgeon, one of whom is always in the building; sleeping accommodations are provided for the latter in the upper story. Hence animals brought for treatment are always sure of immediate attention, day and night. Passing the offices, one comes at once into a large open floor, laid smoothly in asphalt, so that by the use of hose it can be kept perfectly clean. Above the middle of this floor is a shaft leading directly to a sky-light in the roof, so that this area forms a well-lighted operating room, and the opening into the shaft from the story above becomes a gallery whence students can conveniently watch an operation. On this floor a bed is laid whenever an operation of any severity is to be performed, the animal is thrown down upon it, and the anæsthetic administered. For the larger animals ether or chloroform is sometimes used, but for dogs the latter anæsthetic is not employed on account of the cardiac irritability which is almost the rule among the canine race. In many cases where perfect surgical anæsthesia is not required chloral is administered in doses of an ounce to an ounce and a half, according to the size of the horse. This produces a considerable degree of muscular relaxation, and the animal, though not absolutely unconscious, suffers little pain. Of a number of operative cases which I saw, two were of fibroma, one situated on the back and one on the lip; both were considered to be of traumatic origin—the latter caused by an irritating bit. From another horse a scirrhus of the spermatic cord had been removed. The occupant of the adjoining stall was suffering from a long fistula in the neck. It began some two years ago from an abscess which

was opened by the animal's owner, a physician. A fistula remained, into which a rubber catheter had been introduced. Some four months ago this catheter disappeared in the tract and could not be found. On removal at the hospital it was discovered bent upon itself and extending well down by the side of the spine. Being found it was readily removed. Hospital records are made of all cases, with the diagnosis. During the term these records will be kept by the students, and will contain the history, results of physical examinations, and treatment, as in the human hospitals.

On this floor are seven ordinary and four box stalls, one of which, of double size, is padded on the floor and sides, for the reception of any violent or maniacal patient, colic being the principal cause, apart from brain disease, for such violence as to require the padded cell. These accommodations are now being doubled by the occupation of the corresponding space in the second story with stalls. In one corner of this ward stood a valuable Guernsey cow, which was being treated for a leucorrhœa that had existed since her aborting a month ago. Parturition among the lower animals, it may be observed, is by no means the uniformly physiological process which some persons believe to be the rule among all animals except "women of the upper classes." In the cow, for instance, the normal presentation is of the head resting between the fore-feet, but all sorts of malpositions are of great frequency. The number of possible presentations is much greater than that in the human female, is, in fact, almost unlimited, so that obstetrical assistance is often called for. In deformed pelvis, and in the condition known as torsion of the uterus, that viscus cannot empty itself, and the Cæsarean section is the only resource. In many other cases embryotomy is called for. Puerperal fever, puerperal apoplexy, and metritis, all presumably of septic origin, are common, and exceedingly fatal. Fortunately the abnormalities in the mare are less frequent than in the cow, but the smaller animals, probably by reason of their multiple births, are subject to difficulties in their labors. Regarding the frequency of uterine disease, not much seems to be known, partly because of the lack of subjective symptoms to call attention in that direction, and partly because the history of the sexual function is difficult to obtain. Cases of uterine malpositions and of "ulceration of the womb," however, have been observed. The cow alluded to was being treated by astringent and antiseptic injections. The hand was introduced as a guide to the nozzle of the syringe and the solution, chiefly of permanganate of potash, was brought into contact with the whole vaginal canal.

Passing up stairs one comes to the *nurses'* (that is, the grooms') quarters, and thence to the ward devoted to sick dogs. Of these only two were in the hospital at the time of my visit, one suffering from eczema of the back, the other from mange. Skin diseases, chiefly of a parasitic nature, are a frequent occurrence among dogs, and the surgeon in charge remarked upon the difficulty of treating them satisfactorily because of the presence of hair, which prevents the medicament from being brought in contact with the disease, and because the patients, not being amenable to reason, persisted in scratching themselves. In lamenting the unreasonableness of the brute creation in this regard compared with the human species, the surgeon did not appear to be conscious of any irony.

The dogs' kennels are of an average size, of perhaps

four by six feet, the partitions between them being three or four feet high. Arrangement is made for an elevator to bring up the horses to the stalls now being prepared on this floor. A tan-covered incline is also provided as an additional means of escape in case of fire. On this second floor is the pharmacy, a neat, well-appointed room, containing the common drugs, mostly in powdered form. Regarding dosimetry, it was formerly considered that the dose of any medicine for a horse was about ten times that for a man, but the tendency of practice now is to somewhat smaller doses. Some curious facts of toleration were mentioned, for instance, three grains of strychnia have no special effect upon the horse, and the ordinary dose of powdered nux vomica is two drachms, whereas one sixtieth of a grain of strychnia is considered an unsafe dose for a dog. Horses and cows are very tolerant of opium, a drachm of morphia, for instance, being often given to a cow. The favorite method of administration of medicine for large animals is by boluses, which, when containing the bulkier drugs, resemble in appearance a roll of coin. While the tongue is grasped with the left hand, the bolus, carried in the fingers of the right, is pushed back over the tongue into the pharynx. Quinia in drachm doses is thus very readily administered. Another method of giving medicine is by electuary, the viscid excipient being gummed on to the teeth, and allowed to dissolve. Occasionally the "drench" is employed, the liquid being poured into the cheek of the animal while the head is raised. Milk and eggs are used as vehicles for alcoholic stimulants. Horses are sometimes found which in a pneumonia or other acute disease will take milk punch with avidity, lapping it from the pail, while in health they cannot be induced to touch it. Sometimes dogs can be made to take medicine wrapped in a bit of meat, but, as the doctor remarked, one can generally give but one dose in that way to the same dog.

In one corner of this room is a case of surgical instruments. Among these were to be seen, of course, many familiar in human surgery, with others whose use required explanation. Some of the tooth forceps, for instance, are identical with those used by dentists, but with them was a molar forceps of great length of handle, fastening upon the tooth by a screw, and altogether a formidable-looking instrument,—indeed, the extraction of a horse's molar is no very easy operation. The sight of a clamp used for securing the cord in castration suggested the remark by the surgeon that the ligature was uncertain in such cases both on account of the vascular character of the parts in old breeding stallions, and also because of its great liability to set up tetanus. The operation of castration is not so common in the hospital as might be supposed, except in specially valuable animals, being commonly done by the semi-professional gelders, who are to be found in every village, and who go about "cutting." Two sizes of delivery forceps used in bitches and sows were noticed, in size and shape not unlike the placenta or ovum forceps used on the human subject. The male catheters, of flexible rubber, and much curved, were somewhat over a yard long, while a female catheter of metal was shaped exactly like that for the human subject, but, of course, on a much larger scale. Stomach-pumps, enema tubes, etc., presented the same herculean proportions. Of tracheotomy tubes one pattern was exactly like that in common use among our surgeons, but, of course, of a calibre of an inch or so.

Another style, considered preferable, was a self-retaining tube in two parts, the one first introduced turning downward, and the other being passed in at the external orifice of the first, and thence by a fenestra in its upper side directed upward into the portion of the trachea above the opening. The fact that the incision for this operation is made a foot below the larynx in the horse allows plenty of room for such an instrument to be accommodated, and its facility of removal and yet self-retaining power make it a useful instrument. New growths and abscesses involving the laryngo-tracheal region are among the commoner diseases calling for this operation. In this connection it may be mentioned that among the commoner surgical operations practiced in the hospital are "firing" for diseases of the joints and ligaments. In some cases a platinum point heated is driven into the diseased structure. Of carcinomatous tumors, scirrhus, which is common in the spermatic cord, melanoma, found about the anus, and cancerous cauliflower growths, occurring anywhere, are often met. Of these all but the first spread by metastasis or contiguity, and the most thorough removals often grant merely enough respite to enable the horse to be sold by his owner. Fibromata and other benign growths are met with. Fractures are often insusceptible of treatment, especially if of the lower limb and quite oblique. If nearly transverse a starch bandage is applied, and the horse slung, at least partially, so as to keep the weight off the injured foot as far as possible. Some fractures, on the other hand, do well without much treatment. The pelvic bones, for instance, often unite readily under an application of some partially stiff material in the form of a coating over the flank, not sufficiently firm to secure entire immobility. Fractures in dogs are usually easily treated with splints or stiff bandages.

The third floor contains the hay and grain loft and a carriage room, besides the apartments of the assistant surgeon. The basement has space for the accommodation of cows, and also the blacksmith's shop. An observation of the frequent cases of lameness due to careless shoeing will at once convince any one of the important place which the forge-room occupies in the treatment of horses. If ill-fitting shoes and improper paring of the hoof cause deformities, an intelligent application of mechanical principles is the rational method of cure, and its direction belongs as truly to the function of the veterinary surgeon as does the construction of orthopædic apparatus to the surgery of deformities in the human subject. One horse which had been the victim of too much blacksmithing I saw being treated by vesicants with a view to stimulating the growth of the hoof so as to reproduce the deficient structure.

The hospital, which cost about \$20,000, has been erected largely by private contributions, and it is desired to make it self-supporting as soon as possible. To this end a scale of prices has been adopted which should conduce to a liberal patronage of the institution on the part of the stock-owning public. The charge for board, treatment, and medicine for sick horses is two dollars per day, while surgical cases are received at half this price. Dogs are boarded and treated for fifty cents per day, and out-patients are charged for at one dollar per visit. Considering the perfection of the arrangements for light, ventilation, and drainage, the steam-heating, and the general adaptation of means to the end desired, these prices are very reasonable.

Animals sick with more chronic diseases, or suffering from lamenesses or illnesses which require long seasons of rest, are, on the recommendation of the surgeon, sent to the Bussey Farm Hospital, where they can receive all proper care and treatment, together with the benefit of grass paddocks in summer, and a warm straw yard in winter, and where the rates charged are much less than at the Village Street hospital, horses, for example, being treated and boarded for \$4.50 per week. An additional inducement offered to owners of numerous animals is the following: Each subscriber of ten dollars a year may (1) have admitted to the hospitals for medical or surgical treatment an unlimited number of animals, his own property, at a charge for keep and medicines only (not exceeding one dollar a day). (2.) He may procure without charge the opinion of the surgeons of the school as to the treatment of any animal which he may desire to retain in his own possession, whenever an opinion can be given without examining the animal away from the establishment. (3.) He may have ten horses examined as to soundness in the course of the year, and procure the opinion of one of the surgeons thereon, either verbally or in writing, free of charge. Under this contract patients will not be visited, and horses will not be examined for soundness away from the establishment. The facilities thus afforded by this hospital, in addition to a clinic to be held two afternoons in the week, in which treatment is offered for any animals that may be brought free of all charge except the actual cost of the medicines furnished, are likely to secure abundant material for the clinical instruction of the students by a system identical with that employed in the Medical School. Students will be furnished with cases for personal examination, and will be called upon to report them before the class, where the reports will be criticized. A regular course of supplementary instruction will be given in auscultation and percussion, which will afford students an abundant opportunity for acquiring a thoroughly practical knowledge of these methods of exploration. In this connection it may also be mentioned that courses are promised on bandaging, the application of surgical apparatus, and operative surgery. In obstetrics students will be instructed in the methods of performing necessary operations, and will have opportunities during their third year to take charge of cases, while in connection with a course of lectures to be delivered upon the diseases of the eye in the domestic animals, practical instruction will be given in the use of the ophthalmoscope.

It is designed by the officers of this institution to make it the best school of its kind in the country. The course of study which has already been outlined is more extended than that required in any other veterinary school using the English language. Even in the Royal College of Veterinary Surgeons of England, which has been the recognized head of the profession among English-speaking peoples, the course is only three years of eight months each, in all three months less of study than will be required at the Harvard School. The French and German schools, which are under government supervision and subsidy, have a four years' course of study. The excellence of the English school is such that American students of the higher grades are hardly dependent on the Continent for study. To such as do go there, however, France offers fully as much inducement as Germany, Lyons being, perhaps, in as great a degree as any city the veterinary

centre of Europe. At all events the French literature of the profession is considered more valuable than the German.

Turning to this side of the water, we find that there are a number of veterinary schools of more or less excellence, but most of them wanting in practical, if not in ostensible, adherence to a strict matriculatory examination, and none of them approaching the Harvard standard as to the length of study requisite for the degree. Among those schools most strenuous in insisting upon preliminary fitness for the study, and basing the examination, as does the Harvard School, on the requirements of the Royal College, is that connected with McGill University in Montreal, and under the special direction of Professor McEachran. It is now in its seventeenth year, and has about fifty students. It is subsidized by the government, and has a hospital. Its course of instruction covers three years, but each "year" of study comprises only six months, so that its requirement represents actually nine months less of work than that of the Harvard School.

In New York city is the Columbia Veterinary College (not in any way connected with Columbia College), having a curriculum covering only two "years" of five months each; also the American Veterinary College, a department of the University of the State of New York. This school has an equally short course of study, but requires the equivalent of a common school education of its students, and its teaching is said to be good. Its hospital has been one of the most flourishing in the country, accommodating about eighteen horses and five dogs, a smaller capacity, however, as will be seen, than that of the hospital in this city. Among other similar institutions of less importance may be mentioned one at Toronto, and one just inaugurated at Minneapolis.

The Harvard School opens with a number of students in excess of the expectations of its most sanguine friends, and in view of the high standard which it has set before itself there is every reason to predict for it a successful and useful career. Veterinary medicine cannot be learned in six months, and the institutions which insist on prolonged and faithful work will be sure of public respect and patronage.

A NEW DEMONSTRATION OF THE CAVITIES OF THE MOUTH, NOSE, AND PHARYNX.¹

BY THOMAS DWIGHT, M. D.

THE object of this paper is not to chronicle any new anatomical fact, but to make public a method which, I believe, may be called a new one, of demonstrating the cavities of the mouth, nose, and pharynx, more especially the last. I need not pause to point out the importance to the practicing physician or surgeon of the knowledge of the shape, size, and relations of the pharynx, but I may say that, unless I am greatly mistaken, comparatively few possess it. This is due chiefly to the intrinsic difficulty of the subject and to defective methods of instruction. The views obtained by dissection are correct only as to certain points and very delusive as to others. Frozen sections give new and very instructive views, as may be seen by those in the works of Braune, Rüdinger, and Henke, but they

are open to the objection that many sections, and sometimes sections cut in various directions, are necessary to give a correct idea of an organ or space of considerable size, and that the amount of study needed to understand them interferes with their usefulness.

In this connection I may be pardoned a remark on one of the phases of progress in anatomy. We are constantly told that there is little room for further progress, and, indeed, the discovery of new organs is hardly to be expected, but yet within recent years our knowledge of the shape and position of organs has been decidedly extended. As an illustration, look upon this median section of a head, which, I dare say, many would not call antiquated. The fact that the mouth is open perhaps justifies the distance of the tongue from its roof. Notice the great distance of the soft palate from the back of the pharynx, and above all observe this apparently rigid tube, with a diameter a little greater than that of the trachea, rather suggestive of the Hoo-sac Tunnel, but in point of fact meant for the œsophagus. Those who have not the privilege of gazing on this work of art may console themselves by consulting Gray, where they will find almost as bad a figure, or the ninth edition of Quain, which has one taken from Sappey, which in one respect is even worse, for though the mouth is closed the dorsum of the tongue is below the line of the teeth of the lower jaw. Compare these with this enlarged copy which I had made two or three years ago from one of Braune's frozen sections. Observe how the tongue fills the mouth, how the soft palate rests upon it, how near the uvula is to the back of the pharynx, and that the œsophagus, especially at its beginning, is a mere slit between the spine and the trachea. Such a difference in our conception of the relations of important parts marks a real advance in anatomical knowledge of far greater consequence than many discoveries which from their nature are more readily admitted to the honors of anatomical nomenclature.

The demonstration which I am now to present, and which I first showed to the class about a year ago, seems to me to have the merit of showing the relations of the parts with a comprehensiveness that a frozen section does not furnish, and with an accuracy that cannot be obtained by dissection. It is made as follows: The calvaria being removed from an undissected head, and the cranial cavity cleared, a vertical cut is made on each side downwards from the free surface above close to the posterior border of the frontal process of the malar bone to a point behind the lower part of the prominence of the cheek. The anterior end of the zygoma is then divided, and the cut carried down to the bone. A horizontal cut is now begun at the tip of the nose just above the openings of the nostrils, and carried outward to meet the lower end of the first. The septum is then divided, except at its posterior extremity, and a small saw being introduced, the walls of the upper jaw are divided at the level of the last cut, that is, just above the floor of the nasal cavities. It remains to carry the vertical cut across the base of the skull a little in front of the optic foramina and thence downwards to meet the horizontal one. It is evident that they will meet at the lowest part of the pterigo-maxillary fissure, and that all the face above the roof of the mouth will be removed. Theoretically the hard palate remains attached to the pterigoid processes, but the bony connection is so very delicate that it is almost inevitably broken. This ac-

¹ Read before the Surgical Section of the Suffolk District Medical Society, May 16, 1883.

cident, however, is of no consequence, as the parts retain their positions. The posterior part of the septum remains in place.

The separated piece gives an excellent view of the nasal cavities and their relation to the antra and to the orbits, but as these points are not unfamiliar we will pass to the main portion. Here we see the floors of the antra, that of the nasal cavities, and the soft palate. This is no thin veil, as when its muscles are nicely dissected, but a thick fold. We can verify the statement that the hard palate appears to the touch to extend further backward than is the case, owing to the tense fibrous expansion of the *tensor palati*. We can explore the cavity of the mouth, and can study the position of the soft palate all the better from being able to examine both surfaces.

We can now proceed in various ways; perhaps the best is to divide the attachments of the lips and cheeks to the upper jaw, to separate the hard palate from the soft one, and to remove the former. We now see the shape and position of the tongue, and how, except for some small space around the tip and edges, it fills the mouth. We can show how easily, by falling back, the tongue may close the larynx, how short is the distance from the uvula to the epiglottis; how, the mouth being closed, the pharynx is a long tube opening by the posterior nares, and by how slight a movement of the soft palate the upper part of the pharynx may be shut off. The remaining part of the septum being now removed, we can note the shape of the upper region of the pharynx; the obliquity, cutting off the angle at the junction of the skull and spine; the pharyngeal tonsil and bursa; the Eustachian tubes and the deep fossæ of Rosenmüller, caused chiefly by the projection of the cartilage of the tubes. Beneath the soft palate we see the pillars of the fauces and the tonsil. Having examined these points we remove the soft palate and study the deeper parts of the pharynx, which narrow like a funnel, to end apparently in the larynx, behind which there is a very narrow transverse slit leading to the œsophagus. A prominent vertical fold is formed on either side by the posterior pillar of the fauces. Remembering that the œsophagus begins at the lower border of the cricoid we have the opportunity of testing Tillaux's statement that it is fifteen centimetres from the line of the teeth, and any one can easily convince himself of the impossibility of reaching it with his finger through the mouth. No doubt many other points might be alluded to, but my object is simply to call attention to this demonstration, which I think is a very instructive one.

THE EFFECT OF RECUMBENCY ON THE LENGTH OF THE SPINE.

BY E. H. BRADFORD, M. D.

THE so-called physiological curvatures of the spine, not found in the fœtus or in infants unable to sit up, but invariably seen in other individuals, result from the necessity of curves in balancing the trunk with its anterior load of viscera when in the erect position, and in carrying the head erect. These curves are: a long one, with the concavity forwards, involving the whole dorsal and upper lumbar vertebræ, and two shorter ones in the cervical and lumbar region, with the concavity backwards.

Though a great deal has been written on the subject of these curves, the effect of recumbency has received little attention. This, however, is of some theoretical importance in the consideration of the value of the different methods of treating curvatures of the spine. The fact that a person is taller in the morning than at night has been long known, and has been attributed to the expansibility of the intervertebral cartilages. To quote Brodhurst¹: "The effect of pressure on the intervertebral cartilages is shown by the loss of height which is sustained at the end of the day. Thus it is well known that a man of middle stature who remains in the erect position during the day will lose nearly one inch in height, and that this is regained only after he has been in the recumbent position for six or eight hours."

Adams also takes the same view. There "can be no doubt that this diminution in height is entirely due to the compressibility of the soft intervertebral substance;" also, quoting Mr. Bishop: "When the trunk has been kept in the erect posture during the day an adult man of middle stature loses about one inch of his height, which he does not regain until after having remained some hours in a recumbent position."

Mr. Adams found the average loss in height during the day in young and growing persons, as well as adults, varies between half and three fourths of an inch.²

Eulenberg,³ accepting these statements as facts, explains the phenomena, not on the supposition of expansion of the intervertebral substances, after rest (the accepted theory), but under the belief that the muscular system is stronger after the night's rest, and is better able to hold the spine more nearly erect. He quotes the measurements of a French observer, who found that the height is temporarily greater after each meal, and explains the fact in the same way.

E. Noble Smith, in his recent monograph on the Curvatures of the Spine, repeats the statements made by Bishop, Adams, and Brodhurst.

There can be no doubt of the loss of height from the continued erect position. It is, however, also true that lying down immediately lengthens the body to a considerable extent, a fact which has apparently hitherto escaped the attention of writers.

The following measurements illustrate this fact:—

No.	Age of Individual.	Height in Erect Position.	Length in Dorsal Recumbency.	Difference.
1	28	5 feet 8 1-2 in.	5 feet 9 1-4 in.	12-16 inch.
2	40	5 feet 1 6-16 in.	5 feet 2 1-16 in.	11-16 inch.
3	33	5 feet 7 10-16 in.	5 feet 8 1-16 in.	7-16 inch.
4	15	5 feet 8-16 in.	5 feet 1 1-16 in.	14-16 inch.
5	22	5 feet 8 inches.	5 feet 8 10-16 in.	10-16 inch.
6	29	5 feet 8 12-16 in.	5 feet 9 inches.	4-16 inch.
7	30	5 feet 11 14-16 in.	5 feet 4-16 in.	6-16 inch.
8	22	5 feet 11 8-16 in.	5 feet 11 12-16 in.	4-16 inch.
9	31	5 feet 2 inches.	5 feet 2 12-16 in.	12-16 inch.
10	35	5 feet 4 18-16 in.	5 feet 5 5-16 in.	8-16 inch.
11	8 1-2	3 feet 1 8-16 in.	3 feet 2 4-16 in.	12-16 inch.

The result was the same in eight other measurements made, but which were not recorded, and in all cases where such measurements were made.

¹ On Deformities, London, 1871.

² Lectures on Curvature of the Spine.

³ Real Cyclopædie, article Rückenmarks. Krümmungen.

⁴ I am indebted to Dr. A. Post for these measurements.

The following measurements are also of interest : —

Age.	Measurement.	Erect.	Recumbent.	Difference.
85	Evening, 10 P. M.	5 feet 4 13-16 in.	5 feet 5 5-16 in.	8-16 inch.
	Morning, 7 A. M.	5 feet 5 2-16 in.	5 feet 5 14-16 in.	12-16 inch.

They indicate not only that the height of the same individual is greater in the morning than in the evening, but also that the length of the body is greater in the recumbent position in the evening than is the height in the erect position in the morning, as well as the fact that a person is longer in the recumbent position in the morning than in the same position at night.

The above facts can be explained both on the supposition that the intervertebral substances expand, or that the physiological curves diminish on recumbency; but as the amount of height gained by a night's rest is not as great as the length gained immediately by the recumbent position, it seems most probable that the change is due simply to the palpable effect this position would have on the long physiological curve. This view is also supported by the fact that the greatest proportionate gain was in the measurements of the most flexible spine, namely, that of the child; and that too in a spinal column, which having less weight to support would suffer less compression of the intervertebral substances.

A CASE OF COLD ABSCESS.

BY RICHARD COLE NEWTON, M. D.,

Assistant Surgeon United States Army, Fort Cummings, New Mexico.

M. G., a Mexican ranche man, aged twenty-four, presented himself for treatment at the Post Hospital, Fort Stanton, New Mexico, in the month of July, 1881. He lived about seven miles away. He gave the following history: Had always enjoyed good health. Denied all venereal lesions. He was closely questioned on this point, but denied all syphilitic manifestations. He was a very intelligent man, and I believe spoke the truth. I think, however, that he had a hereditary specific taint, although I never could obtain other evidence of it than the course of this illness. Some months before I saw him, after several hundred miles of hard riding, herding, and driving wild cattle, the patient found that he had bruised his side by wearing a pistol so that the handle rubbed against his body. After this a swelling appeared and increased gradually in size. In April, 1881, he consulted Dr. Lane, of White Oaks, New Mexico, who opened an abscess in the same position as the one to be described, and evacuated a large quantity of pus. The incision was allowed to close, and no further treatment seems to have been pursued.

On physical exploration I found the scar of the former incision. This had evidently been made into an abscess which now moderately distended the right half of the epigastrium, and the left of the right hypochondrium. The scar was just below the xiphoid cartilage. The swelling was so sensitive that no attempt was made to map it out exactly by percussion and auscultation. A considerable deposit of pus was suspected in or beneath the chest wall, overlying the right lobe of the liver. There was no local heat nor redness, and no throbbing nor bruit, merely a dull pain and sense

of weight. Physical examination of the heart and great vessels and of the lungs gave negative results. There was no cough or other symptom of pulmonary trouble. Patient complained only of weakness and pain in his side; both of these troubles were increasing. He was pale and anæmic to a great degree, and had lost much flesh. Some hectic flush on cheeks. Pulse rather feeble. Tongue pasty, with thin, whitish coating. Bowels regular. Appetite fair. Cod-liver oil and mixed treatment (pot. iod., ten grains, and hydrag. bichlor., one twelfth grain, three times a day) were prescribed, and patient was told to paint the swelling with iodine.

During the following month the swelling gradually increased in size. In September, during my temporary absence from the post, the patient was seen by my colleague, Dr. Francis H. Atkins (late of United States Army), and was found weaker, and suffering more pain. The abscess seemed to be pointing at the site of the former incision (a little below and to the right of the xiphoid cartilage). He was given a tonic and morphia pills (one eighth grain) to allay the pain.

On the 25th of September I was summoned in haste. I found the man much worse than I had ever seen him. Something must be done, and I concluded that evacuation of the abscess was the only course. Dr. Atkins strongly suspected a hepatic abscess, and that did seem more reasonable than a cold abscess of the chest wall in this position. However, I plunged a scalpel into the pointing part, and followed this by a trocar and canula. About one and one half pints of sanguinolent, inodorous pus were extruded in good part by pressure. The incision was more than an inch in depth. Blood from this, and a grumous, blackish material also flowed into the basin. All these matters soon coagulated spontaneously. No further interference with the abscess was deemed prudent. A pad of oakum was bandaged against the orifice. The man was told to continue his tonic, and take five grains of quinine morning and evening in addition.

September 27th. Patient felt a little better. The incision was nearly healed. I forced the nozzle of a universal syringe into the wound, and thoroughly washed out the cavity with water *pretty strongly carbolyzed*; about one half as much matter came away as at the opening of the abscess two days before. The discharge appeared the same as the other, but did not coagulate. A probe entered the cavity for about five inches, where it had considerable play. To reach the bottom of the cavity the probe must pass downwards for about two inches, then *around* the conjoined cartilages of the right lower ribs, then directly to the right and somewhat downwards. The difficulty of measuring the exact size of the abscess cavity was insurmountable, or nearly so, without an anæsthetic, and the position of this cavity, impinging as it must upon the liver and the peritonæum, caused me to be extremely careful about my explorations. Before opening the abscess I had laid down a rule for myself to be very cautious and gradual in all my proceedings.

A drainage tube was now introduced with some difficulty, the rise and fall of the chest walls during respiration tending to extrude the tube. After a while I substituted a plug of oakum for the rubber tube, and liked it much better. There was now little doubt that the condition was that of a simple cold abscess, not communicating at all with the liver. The only other possibility was that it depended upon a malignant

growth. The discharge to gross appearance might favor this view, as well as the general condition of the patient. His age, however, was in his favor. I have never to my recollection seen such contents of an abscess cavity except once, in a case of Pott's disease, in which there was extensive bony necrosis. Necrosis of bone or cartilage in this case was carefully looked for, but never found. It is, of course, possible that such a condition may have existed, and from the peculiar conformation of the abscess cavity have eluded discovery, but the subsequent course of the case renders this hypothesis very improbable, and that of carcinomatous growth quite so.

To resume our history: The patient was ordered to take twenty grains of quinine daily and a pill (one eighth grain) of morph. sulph. occasionally. The tonic mixture was suspended. There had been some febrile symptoms present the two previous evenings.

September 28th. Patient sent for me in haste. Said that he had passed a miserable night. That the discharge from the wound had stopped toward evening; that his belly had begun to swell; and that he was in great pain until three A. M., when the discharge was reestablished spontaneously with relief to the pain. Had had fever toward night, and had sweat profusely before morning.

He was very weak and distressed. Facies dark and anxious. Hectic flush on cheeks. Tongue pasty. Pulse feeble. Clammy perspiration on his body. He evidently considered himself in *extremis*, and not without reason. Ordered to partake freely of milk punch, and to take thirty grains of quinine a day. The wound was unmolested except to change the dressings. A large quantity of the same grumous material found upon these. This was now quite fetid.

September 29th. The patient feels better and can sit up in bed. The drainage tube is now in place and the discharge is free. Gave a hypodermic injection of Magendie's solution, and washed out wound with carbolyzed water. I now think that pure carbolic acid was used in excess; so much was used because it seemed well to stimulate the "pyogenic membrane," so-called, that presumably lined the interior of this cavity. Ordered ten grains of quinine and one eighth grain of morph. sulph. at three and at six P. M., with a view of anticipating and controlling the evening rise of temperature that seemed to follow the washing of the wound.

October 1st. The patient was usually seen only every other day, because he was so far away from the Fort. On this date he said that about one hour after the last washing out of the abscess he experienced a chill, followed by fever which lasted about four hours, terminating in a sweat, after which he fell asleep and slept until morning. No chill or fever on the next day. To-day feels cheerful and talks of getting out. Appetite better. Bowels regular. Marked improvement. The discharge is considerably diminished; is still very fetid, though it is beginning to look more like laudable pus; foul gas escapes with the wash water.

October 3d. Washed wound again. Other treatment same, except that the plug of oakum has taken the place of the drainage tube, and quinine has been decreased to fifteen grains daily.

October 5th. Found the man walking about his door yard. His wound is now discharging a moderate amount of laudable pus. There is still some foul smelling gas which escapes with the wash water. He

was ordered to resume his tonic (two grains quin. sulph., one thirtieth grain strychn. sulph., two drops ac. nit-muriat., twenty drops tinct. ferri chlor., one half ounce syr. et aq. q. s. ut ft. 3ss.) four times daily.

October 30th. About the middle of this month the patient was put on the pills of the protiodide of mercury (one fifth grain), one pill three times a day. These produced some tenderness of the gums in five or six days. They were discontinued, and cod-liver oil given again. On this date the mixed treatment was added to the oil. The probe still passes into the abscess cavity for over three inches, but its play is much restricted. The discharge is now laudable (sweet smelling) pus. The cavity is slowly filling up. The pain attending the washing of this cavity has steadily increased, so much so that the man will scarcely allow me to do more than pretend to wash it out. This appears to be a good sign; at least, I think that it means that a healthy granulating surface is more sensitive than the pyogenic membrane which used to line the cavity.

November 13th. Have not seen the patient for several days. He had driven nine miles away when I called. His wife reports that he is very well, that he has no pain, and that the discharge is very slight.

November 28th. The man came into the post. A "warm abscess" had formed in median line just above the orifice of the "cold" one; and had opened spontaneously into the old sinus. Should judge from the man's account that about a pint of laudable pus had escaped from the new abscess. His general condition continues to improve. Complains that the mixed treatment which he has taken for a month, has made his jaws sore. I substituted ten grains kali. iod. and one fluid ounce ext. sarsapar. three times a day. Esteem it a good indication that, if the man must have another abscess, he can now have an acute one, with "heat, swelling, pain, and redness."

February 3, 1882. Have heard of the patient from time to time. He has been able to attend to his business. On this date he wrote me from White Oaks (thirty miles away) that he was sick with a bad pain in his left side, and was "bad off." I did not see him, but in a few days he was well again.

When I left Fort Stanton, 11th March, 1882, the man was at work as a teamster, and was, I presume, all right.

Remarks. I now believe that the "chills and fever" complained of after the washing of this cavity, especially at first, were due to carbolic acid poisoning, for the following reasons:—

(1.) I used the acid rather extravagantly, hoping to stimulate the walls of the cavity to healthy action.

(2.) If not so produced, these manifestations were due, probably, to hectic (septicæmia) or to malaria. If due to either of these causes, they would hardly have followed the washings, which were at irregular intervals, so closely, and have appeared at no other times (except slightly on the day of the first incision and its successor).

(3.) As the wound grew healthier the pain of the washings increased, but the bad after-effects diminished, because the healthier surface, while more sensitive, was less absorbent. It should be added that the patient's general condition was so far improved that he could withstand deleterious influences of any kind better. On the other hand, on account of the pain, the patient, although very tractable, would not permit the later washings to be so thorough as the earlier ones.

(4.) Had these symptoms depended upon the admission of air to the wound and the decomposition of the effete matters, why was not the evening following the opening of the abscess the worst time, instead of that following its first washings?

There never was a counter-opening made.

The urine was not examined, as it certainly would have been if carbolic acid poisoning had been suspected at the time.

No pulse nor temperature record was kept.

The case could have been much more satisfactorily treated had not seven miles of bad country intervened between the surgeon and his patient.

The amount of carbolic acid (pure) used was two to three drachms to a large basin of wash water. Carbulated vaseline was used on the dressings.

The case has seemed to me worthy of record:—

(1.) Because I think that it furnishes another caution to the already considerable number reported that carbolic acid must be used with a great deal of circumspection.

(2.) Because this abscess simulated hepatic abscess so closely from its peculiar position.

(3.) Because it is quite likely that hereditary syphilis complicated this trouble, although I admit that there is no proof of this supposition in anything I have written.

(4.) Because, while it shows that cold abscesses must be treated with great respect, it, I maintain, goes to demonstrate that as a rule they must be incised. And

(5.) I think it also helps to show that surgery (operative) is only a handmaid to physio.

RECENT PROGRESS IN NERVOUS DISEASES.

BY S. G. WEBBER, M. D.

EMOTIONAL DISTURBANCE IN HEMIPLEGIA.

J. Luys¹ has noticed the exaggeration of emotional disturbance most decidedly in cases of left hemiplegia. The lesion is located in the middle regions of the brain on the right, and such as give rise to paralysis are from destruction of the convolutions of the insula, of the external capsule, and of the gray substance of the corpus striatum. In most of the cases observed secondary descending degeneration could be traced as low as the medulla. There was also an extension of the lesion backwards so as to implicate the bundle of fibres of the corona radiata, which passes to the posterior portion of the optic thalamus and the first temporal convolution, at the deeper and upper part of the fissure of Sylvius. Luys locates here the lesion which causes the emotional disturbance.

EPILEPSY.

William Alexander² reports five cases in addition to three reported November 19, 1881, where he tied one of the vertebral arteries in severe epilepsy which had resisted other treatment. As to three cases previously reported, he says that they remained free from relapse. In another case, not fully reported, in which the epilepsy was complicated with maniacal symptoms after, or in place of, the fits, these maniacal symptoms subsided as well as the fits, but a relapse took place in

¹ Recherches Nouvelles sur les Hémiplegies Émotives, L'Encéphale, 1881, page 378.

² On the Cure of Epilepsy by Ligature of the Vertebral Arteries, Medical Times and Gazette, March 11, 1882, page 250.

regard to both symptoms. The other vertebral was then tied without any bad effect, and both epilepsy and mania entirely disappeared, though after a while the patient had one or two slight fits without loss of consciousness and no mania. Five new cases are reported, and the author mentions that he has ten others under treatment. In three he has tied both vertebrals simultaneously without any bad effects. In all the amelioration has been decided, whether we have regard to the reduction of the fits or the improvement of the mental powers.

Dr. Radcliffe³ reviews the history of the introduction of bromide of potassium in the treatment of epilepsy by Locock, himself, Brown-Séquard, and others. He says he rarely gives more than forty-five grains a day. The bromide does not act kindly in cases where the memory is bad and the mental power generally enfeebled. It is not advisable to go so far as to produce "bromidism." In cases of *le haut mal* with much mental enfeeblement this medicine is very likely to be hurtful even when only given in moderate doses, and in the majority of cases of *le petit mal* the good to be done by it is barely appreciable. He thinks the bromide of potassium, bromide of sodium, and bromide of ammonium are very much on a par as to remedial value, while the last, having rather a larger proportion of ammonium, may be preferable. Iron he has found injurious. He thinks iodide of potassium and bicarbonate of potash may be useful adjuvants. Arsenic, hypophosphite of soda, and chloride of ammonium may be advantageously associated with the bromides. The hypophosphite of soda, he thinks, nearly doubles the remedial value of the bromides. As a tonic with bromides he prefers quinine or bark, or especially nuxvomica.

Speaking of diet, he says that his experience teaches that an epileptic is much more likely to get on satisfactorily who is not afraid to take a liberal allowance of fat, or butter, or cream, and who makes a point of stinting himself in nitrogenous articles of food, in butcher's meat more especially. He objects to the use of much milk if other food in plenty is used, but he is in favor of genuine "milk diet." He recommends a trial of buttermilk or sour whey in place of fresh milk, or rum and milk with the ordinary diet. He advises that the patient should have some occupation for his mind, and education should not be neglected. Sleep should not be too prolonged.

Robert Saundby⁴ advises the combination of the bromide salts with each other, giving the daily dose in divided portions so that the influence of the drug is kept up throughout the day. He invariably adds ten minims of tincture of digitalis to counteract any depressing tendency, enjoins attention to the bowels, and abstinence from alcohol, restriction as to animal food.

The most useful adjunct to the bromides is oxide of zinc, three to five grains, combined with one sixth of a grain of extract of Indian hemp.

Charles E. Beevor⁵ finds no loss of weight after epileptic fits. He carefully weighed patients in the morning, and again after the fit. In six cases of hystero-epilepsy, treated in a similar manner, there was no alteration in weight.

³ Medical Annotations concerning Epilepsy, Paralysis, and Other Disorders of the Nervous System, Practitioner, February, 1883, page 89.

⁴ The Treatment of Epilepsy, Practitioner, February, 1883, page 105.

⁵ British Medical Journal, July 8, 1882, page 56.

François-Franck and A. Pitres¹ have given a valuable contribution to the study of epileptiform convulsions of cortical origin. They experimented upon animals, and found that these convulsions can be produced experimentally only upon a limited number of species, the cat, dog, and ape being easily influenced, the rabbit and guinea-pig only with difficulty; in birds, batrachians, and fish no convulsions could be produced. Electricity was the most likely to give rise to the attacks, coarser mechanical irritations having effect only when the cortical substance was inflamed, and so abnormally irritable. If the irritation was applied to the white medullary substance, just below the cortex, to the basal ganglia, or to the internal capsule, there was simple contraction of sets of muscles, no epileptiform convulsions. The motor region of the cortex was most readily excited to cause convulsions; parts removed from that region would not cause these unless the irritation was very intense. The excitability of the cortex is increased by strychnia, absinthe, atropia, cannabine, and by a slight degree of inflammatory irritation. It is diminished or destroyed by inhalations of ether or chloroform producing anaesthesia, by intravenous injections of chloral, by asphyxia, by applying ether spray directly to the cortex.

The epilepsy produced by experiments upon the cerebral cortex may be transmitted to the offspring, in whom, however, no appreciable cerebral lesion is to be recognized.

Unverricht² reports the result of his experimental and clinical investigations in regard to epilepsy. His conclusions agree in many respects with those of Franck and Pitres, though some points have been more fully elaborated.

PARALYSIS IN INFANTS.

W. R. Gowers³ and W. H. Barlow⁴ give interesting remarks upon disease of the anterior cornua of the cord. Names are rather multiplying for this affection, and confusion is likely to arise therefrom. As knowledge of obscure nervous lesions increases, it may be well to change names, but a too early change is undesirable; in these two papers are given three different names, besides these we have *anterior poliomyelitis* and *cornual myelitis*; the name selected by Gowers is preferable clinically, the two last names, one the equivalent of the other, are preferable if a pathological basis of nomenclature is chosen.

Gowers calls to mind our ignorance of the nature of the process in the spinal cord, and appeals to the general practitioner to investigate the point; he also can increase our knowledge of the relations of the disease to teething by supplying facts in regard to the age of patients and the state of dentition at the time of the onset. Barlow believes it is the condition of the nervous system at the period of the dental evolution that predisposes to the attack, by rendering the body more susceptible to external impressions, rather than the evolution itself. Barlow gives further statistics as to the season when the disease is most frequent. He finds that of 111 cases thirteen occurred in June, twenty-six in July, twenty-two in August, ten in September,

equal to seventy-one in the hot months; that is, more than half. This agrees with the observations made in this country by Dr. Wharton Sinkler.

Barlow also gives the ages of 149 patients at the time of the attack: fifteen under six months; twenty-seven between six and twelve months; fifty-two between one and two years; forty-two between two and five years; three between five and seven years. Gowers mentions one patient who was probably attacked *in utero*; also one, a man, more than seventy years of age at the time of the attack. Barlow found that convulsions preceded the paralysis in fourteen out of 149 cases.

Gowers calls special attention to the early use of electricity as a means of diagnosis, using it six or eight days from the onset. The faradic current is to be used. If the nerves are degenerated the muscles do not contract under its influence; the motor nerves depend upon the large nerve cells of the anterior cornua for their nutrition, and the nerve fibres undergo degeneration when the cells are destroyed. The widespread paralysis seen at the onset depends on damage too slight to cause degeneration, and it soon passes away. The muscles thus affected present no change in their reaction, and do not waste; those which derive their nerves from the part most damaged, show the reaction of degeneration. By the electric examination not only is the diagnosis established, but we can pick out and foretell which muscles will be ultimately most affected.

Gowers also calls attention to the value of an exact record of the electrical reactions of muscles as a method of studying the nerve supply of muscles and of recognizing those which physiologically act together.

For treatment in the earliest stage Gowers suggests that attention should be directed rather to the morbid process — the internal inflammation — rather than to the seat of that process; that aperients, diuretics, and agents which act on the vascular system should be used rather than nervine remedies; during the period of recovering using the latter and electricity and skilled rubbing.

James Ross⁵ reports several cases with remarks. The spasmodic paraplegia may be due to disease of the spinal cord occurring during the birth of the child, yet all cases cannot be explained in this manner. There may, in cases not thus caused, be an arrest of development of certain portions of the nervous system. It would appear, however, that arrest of development of the pyramidal tract is associated in the cases hitherto examined with a congenital lesion in the motor area of the brain, and it will probably be found that these conditions always coexist. If that be the case, we may expect that at least a considerable proportion of cases of spastic paraplegia, are really cases of bilateral hemiplegia, caused by a parencephalous defect of the cortical motor centres of the affected limbs, and arrest of development of the fibres of the pyramidal tract, which would have sprung from these centres. He thinks clinical observation shows that the brain is affected.

SYMMETRICAL GANGRENE (SYMMETRIC ASPHYXIA) OF THE LEGS.

M. Weiss, of Prag,⁶ gives first a historical résumé

⁵ On the Spasmodic Paralysis of Infancy, *Brain*, January, 1883, page 473.

⁶ Ueber sogenannte symmetrische Gangrän (Raynaud's "Locale Asphyxie und symmetrische Gangrän"), *Zeitschrift f. Heilkunde*, vol. iii., 1882, p. 233.

¹ Archives de Physiol. Norm. et Path., July, 1883.

² Arch. f. Psych. und Nervenkr., vol. xiv., 1883, p. 175.

³ Remarks on Acute Spinal Paralysis, *British Medical Journal*, May 20, 1882, p. 729.

⁴ Remarks upon Regressive Paralysis; chiefly as seen in the young subject (so called infantile paralysis, acute spinal paralysis, etc.), *ibid.*, page 734.

of the subject, with a brief abstract of the cases which have been previously reported. He then gives a long account of a patient who was affected with the disease, the parts attacked being the fingers and toes, the left cheek, the sacral and gluteal regions. This is followed by a brief sketch of the symptoms, course, and duration of the disease.

The so-called symmetrical gangrene differs widely from other neuroses in the disturbance affecting nearly the whole of the nervous system, but especially the vaso-motor nerves, and in the gangrene which is generally localized in the terminal phalanges of the fingers and toes. Like other neuroses, the symmetrical gangrene almost always appears in paroxysms. In many patients there is a prodromic period, in which appear psychical symptoms of a depressive nature. Without any cause there is a sense of unrest, and a change of character; a patient who had been previously good-natured and happy becomes surly and peevish, withdraws within himself and avoids contact with those whom he formerly sought, even his own children; continual sighing and frequent tears show how serious is the disturbance. Sleep is restless, broken by frightful dreams. Appetite is poor, digestion is difficult, and the slightest excess beyond the demands of appetite is followed by severe gastric crises, such as are seen in ataxia. The special senses are also affected, hearing becomes difficult, taste is altered, sight is dimmed. The intellect is not affected, there are no hallucinations; motor power is not disturbed. Soon peculiar sensations are felt in different regions of the body, and a paresthesia limited to one or both corresponding limbs attracts attention to the patient's condition. This does not continue long; the affected limb becomes the seat of severe neuralgic pain, which persists without intermission, almost without remission, and affects unfavorably the nutrition. With the advent of the pain, most probably because the patient's whole attention is absorbed thereby, the psychic disturbance becomes of secondary importance; only one wish remains — to be freed from the pain. These pains always precede the severer attacks of the disease, even when there is no mental disturbance; they are at first spread over the whole extremity, later, however, they are concentrated in that portion which is to suffer mortification. With the pain appears a marked vaso-motor disturbance — ischemia, cyanosis, or redness on the fingers and toes of the affected limbs, sometimes also in other parts, and when the vascular disturbance becomes habitual it acquires a greater intensity and extent. In some patients manifold trophic disturbances are seen; erythematous spots of variable size appear in spots on the affected limbs; there may be neurotic synovitis with infiltration of the subcutaneous cellular tissue above and below the affected joint, or increased growth of the epidermis, morbid changes in the nails, atrophy of certain muscles, with diminution of their direct and indirect irritability for both forms of electrical current. There may also be symptoms of paralysis of the cervical sympathetic, disappearance of the fat from the cheeks. Finally, there is gangrene of the terminal phalanges of individual fingers or toes, rarely of other regions of the body.

This gangrene begins thus: a line of the skin, or a round spot, from the size of a pin's head to a pea, on the pulp of the last phalanx (more rarely on the dorsum) acquires an appearance resembling parchment, as if the spot had been touched lightly with a white-hot iron. This spot becomes darker until after one or

two days it is black, or blisters filled with bloody serum form, and after they burst the excoriated spot acquires a dry, black appearance. In either case the further course is the same, and the only variations depend upon whether the gangrene shall attack only the superficial cutaneous tissues or the other deeper structures. In the first case after four or five days the dried epidermis falls off, leaving, perhaps, a superficial ulcer, which heals slowly; but if the deeper structures are attacked, the whole or half the phalanx is mummified, and with more or less inflammatory reaction is separated from the healthy tissue. After this is removed the stump cicatrizes in one or two months' time. The stump is usually rather club-shaped and irregular from infiltration of the subcutaneous tissue. The duration of the entire attack from the first prodrome to cicatrization is two to four months. The process is unaccompanied with fever, and the other functions are normal; the pulse is only somewhat more frequent than normal; the general nutrition is disturbed by the pain and sleeplessness.

The author considers the reasons for believing this affection to be a neurosis of the vaso-motor system, and those for looking upon it as a trophoneurosis. His conclusion is that the disease is primarily a vaso-motor affection; that the trophic and other phenomena are secondary.

Hastreites has written on the same subject.¹

LOCOMOTOR ATAXIA.

A. Eulenberg² considers the curability of locomotor ataxia. In 300 cases he has had three recoveries, the patients remaining well for several years, in one case eight years. The characteristic symptoms disappeared, and there remained only insignificant traces of partial anæsthesia. The proportion of cures is small, but he recalls the fact that in a disease that has been considered incurable a proportion of recoveries so small as one in 100 is encouraging. The treatment was not the same in each case. He used galvanism, hydrotherapy, and nitrate of silver; the silver was used in two of the three. He recommends the subcutaneous injection of a silver albuminate.

HEREDITARY ATAXIA.

L. Rüttimeyer reports³ several cases resembling Friedreich's hereditary ataxia. Eight were in one family, and three in another. It appears sometimes as early as four years, sometimes as late as the eighteenth year. The disease is quite different from progressive locomotor ataxia; there is not the lancinating pain; the ataxic gait appears early, and soon there is incoördination of the upper extremities; the speech shows disturbance of coördination, and there is ataxic nystagmus; tendon reflex is absent; there is often a slight diminution of sensibility; muscular sense is not disturbed; at length there is paraplegia with contracture; bed-sores rarely form; there is no disturbance of bladder; the mind is not affected.

Rüttimeyer thinks the disease affects the spinal cord primarily, the medulla oblongata and corpora quadrigemina secondarily. Dr. William A. Hammond has also suggested that the medulla oblongata may be the seat of the lesion in this affection.⁴

Hospital Practice and Clinical Memoranda.

DEATH FROM CARBOLIC ACID.

BY D. HOMER BATCHELDER, M. D.

MR. DAVID F., Scotchman, a man of respectable character and habits, fifty-six years of age, whose occupation was that of a designer and engraver. He was employed as such at the print works of A. & W. Sprague Manufacturing Company.

On the morning of the 23d of January last he arose and took his morning meal as usual. He then started to take the street car, which passed about half-past six A. M. The car had got by, and he stepped back into the house to wait ten minutes for the next car. During that time, he said to his wife, he did not feel very well, and would take a little wine before he went. He took what he supposed to be the bottle of wine and drank from it, no one knows how much, and immediately exclaimed in a broken manner, "My G—, what have I taken?"

He was at once thrown into the most excruciating agony. On examining the bottle, it was found that there were two pint bottles standing side by side on the shelf, one containing sherry wine, the other carbolic acid, full strength.

They undertook to administer some remedies themselves, using nearly an hour's time before they called me, although my house stands not over thirty rods from where the accident occurred.

When I reached the house, I found his eyes were rolled upward, cornea not visible, limbs rigid, with a very copious discharge of fibrinated mucous from the mouth, mingled with detached portions of the mucous membrane, while the pulse indicated nothing but a slight flutter or tremor of the heart. In less than fifteen minutes subsequent to my arrival life was extinct.

I am not aware of any specific antidote in cases of this kind of poisoning. This is my second case of poisoning from carbolic acid. Both were fatal, for I did not in either case arrive till the patient was in a state of *articulo mortis*.

My course would be, however, were I there in season, to put into the stomach as large a quantity as possible of either castor or olive oil.

As the effect is immediately destructive to the mucous membranes, I should say that in fifteen minutes after the poison had been taken, the passage to the stomach would be closed, and the only alternative would be to force it by the pump. But I am confident that after the expiration of fifteen or twenty minutes at most, all manipulative means of this kind must certainly fail to save life. The destruction is so immediate, so extensive, involving tissues which are so vastly important to life, that its highway is completely obstructed, and death is the only relief in such cases.

However, if there are any members of the profession who have had such cases to deal with, — I mean cases like these, where persons have drunk down the concentrated carbolic acid in quantity as those I have narrated, — it is to be hoped they will give a synopsis at least of their experience in the premises.

Reports of Societies.

PROCEEDINGS OF THE AMERICAN DERMATOLOGICAL ASSOCIATION.

SEVENTH ANNUAL MEETING, HELD AT THE SAGAMORE HOTEL, LAKE GEORGE, AUGUST 29, 30, AND 31, 1883.

REPORTED BY HENRY WILE, M. D.

MORNING SESSION.

THE meeting was called to order by the president, DR. R. W. TAYLOR, of New York, who, in a short address, welcomed the members assembled.

The first paper, entitled, —

TREATMENT OF ACNE,

was read by DR. PIFFARD, of New York. The writer advocated the internal use of calcium sulphide. In the treatment of the acute papule he advised puncture of the lesions, together with application of hot water, after which some soothing ointment, as of belladonna or stramonium, especially the latter, in the form of the fluid extract made from fresh leaves gathered in the fall. The base of the ointment should be benzoated lard or oxide of zinc. In using the calcium sulphide it should be pushed until additional lesions appear, when it should be stopped. Comedones should be treated by pressure with the finger nails or key. In acne indurata ergot was advised.

DR. ATKINSON, of Baltimore, failed to obtain good results with calcium sulphide or ergot.

DR. VAN HARLINGEN, of Philadelphia, recommended the following paste for the treatment of the comedones: Glycerine three parts, acetic acid (U. S. P.) two parts, kaolin four parts, originally suggested by Nuna.

DR. ALEXANDER, of New York, had good results from the use of calcium sulphide in the pustular variety of acne. Ergot seemed only to diminish the redness.

DR. SHERWELL, of Brooklyn, said that he noticed some benefit follow the use of ergot in the pustular form in the female, where there seemed to be exacerbations at the menstrual periods. He regarded this form as a reflex process, and gave ergot on purely empirical grounds, and with good results.

DR. PIFFARD, of New York, thought that the beneficial results obtained in the treatment of acne depended upon the amount of irritation an agent created in the lesions. In the summary Dr. Piffard described a case which he regarded as one of the worst that ever came under his notice. The patient was treated for uterine disorder by a gynecologist, at the same time was given ergot internally and mercurial ointment externally. She recovered.

DR. TAYLOR, of New York, thought that the local treatment was of paramount importance, the internal treatment subsidiary. He placed great reliance on the use of alkaline salts. Rochelle salts ʒi. to ʒij., acetate of potash ʒss., three times a day in a wine-glass of water. In the indurate variety he punctures the lesions and applies acid nitrate of mercury, one part to eight parts of water. Where rosacea is present he advises the following: Chrysarobin ʒss., flexible collodion ʒi. He has seen no benefit follow the use of ergot. As valuable agents he recommends mercurial ointment ʒss., cosmoline ʒi.; also iodide of zinc gr. v. to gr. xv., adipis ʒi.

— A crematory for persons dead of infectious diseases is recommended by the grand jury of New Orleans.

DR. STELWAGON, of Philadelphia, recommended a lotion composed of zinc sulphate, potassium sulphuret, $\text{aa } \text{ʒi. to water } \text{fl}\text{ʒiv.}$

The next paper, entitled, —

GENERAL EXFOLIATIVE DERMATITIS,

was read by DR. GRAHAM, of Toronto. Dr. Graham gave a brief *résumé* of the literature, which he claimed was not extensive. He had had four cases. He thought that the disease existed in two varieties: first, dermatitis exfoliativa rubra; second, dermatitis bullosa et exfoliativa. The first might include pityriasis rubra, the second pemphigus foliaceus.

DR. HARDAWAY, of St. Louis, described a typical case of pityriasis rubra where arsenic was used for months without benefit. The use of the tincture of the chloride of iron gave good results.

DR. ATKINSON, of Baltimore, thought it impossible to describe a distinct disease under the name general exfoliative dermatitis. He thought it was symptomatic, and the result of different causes, especially neurotic; also, due to the use of drugs. Cases of recurrent scarlet fever have been found to be due to small doses of quinine.

DR. FOX, of New York, thought it advisable to group these various affections under this head with the exception of pityriasis rubra, which he thought was a distinct disease, and he could recall but two cases.

DR. MORROW, of New York, thought that the disease was essentially a trophoneurosis, and he has seen good results follow the use of arsenic.

In the summary, DR. GRAHAM said that he was inclined to regard the disease as a trophoneurosis, as in one case presented the general eruption was preceded by a herpes, which is of neurotic origin.

DR. TAYLOR, of New York, called attention to two cases of the disease, the photographs of which were exhibited. The first case, a lady, having suffered much from malaria, was accustomed to take quinine, and, according to her statement, she had ten or eleven attacks of scarlet fever. Quinine was given, and in twenty-four hours she had a scarlet eruption, followed later by desquamation. The second case, a boy aged nineteen years, had poor family history. Scaly eruption began on the wrists; soon extended to face, chest, and whole body. Desquamation was extensive. Lesion on the buccal mucous membrane, tongue; also fissures at the angles of the mouth, but these were not of a syphilitic nature. The subdermal tissue was not infiltrated, the process involving only the epidermis.

DR. PIFFARD, of New York, suggested the use of jaborandi in Dr. Taylor's last case. He had used it with success in ichthyosis.

DR. FOX, of New York, recommended the use of chaulmoogra oil.

The next paper was read by DR. STELWAGON, of Philadelphia, the subject being, —

IMPETIGO CONTAGIOSA.

The writer gave an account of the opinions and theories held by different authorities as to the nature of the disease. He was inclined to regard the disease as contagious and occurring in epidemics, also as systemic in character, in a way similar to variola and varicella, and that it had no connection with vaccination.

DR. HARDAWAY, of St. Louis, considered it an independent disease, on account of its contagiousness,

and, as Dr. Stelwagon says, its appearance in epidemics.

DR. ATKINSON, of Baltimore, claimed that many pustular eruptions seemed to acquire a contagious element in warm weather.

DR. ROHÉ, of Baltimore, said he felt convinced of the inoculability of the pus of impetigo contagiosa, having performed experiments upon himself.

DR. FOX, of New York, also believed the pus to be inoculable, and that the disease had no connection with vaccination.

DR. PIFFARD, of New York, said that he had seen a series of cases in a certain family follow vaccination. He thought the disease was of a parasitic nature. He had found a fungus which was the same as that found in vaccinia. To render the fungus visible he employed a solution of caustic soda, one part to five.

DR. TAYLOR, of New York, did not regard the disease as systemic. In sixty cases, observed by himself, the affection commenced about the nails and face. He regarded the disease as spreading by contagion; it always appears on parts accessible to the hands.

In the summary Dr. Stelwagon argued that the disease was systemic, in the nature of variola, varicella, etc. Five hundred microscopic examinations of the pus were made; three times the fungus of Piffard was found, ten times the fungus of Kaposi.

The next paper, entitled, —

MULTIPLE CACHECTIC ULCERATIONS,

was read by DR. ATKINSON of Baltimore.

The writer described in detail the case of a child upon whose fingers, legs, and, later, the face, appeared certain ulcerative lesions, which for a short time remained inactive, then assumed an active form, when the tissues were literally melted away by the process. The two terminal phalanges of the right forefinger were separated from their attachment and thrown off. The other lesions healed under treatment, leaving scars. The author regarded the process as a neurosis resulting from a disturbance of the vaso-motor centres which in turn caused nutritive changes.

DR. VAN HARLINGEN, of Philadelphia, described a case in which the patient, an old man, having suffered amputation of the left leg, exhibited lesions over the knuckles of the right hand, consisting of smooth blackened excavations the covering of which was later thrown off as a slough. On the right forearm was an ulcerated lesion about two inches by one and one-half inches surface, of a grayish color, and covered with a scant amount of secretion. The lesions remained inactive up to the death of the patient, which occurred in a few weeks.

DR. TAYLOR, of New York, presented two cases, one a child with an ulcer on its back, size of a silver quarter dollar. In spite of treatment the ulceration extended downward to the fascia and muscle, forming a lesion four inches by two and one half inches. By means of diet-tonics a cure followed. The other case was a woman. She appeared with a swelling on her nose, upon which was a bulla; the lesion began to break down, involving the surrounding tissue, and in healing left a contracted cicatrix. There were similar lesions on the fingers.

EVENING SESSION.

The first paper was read by DR. VAN HARLINGEN, of Philadelphia, subject, —

EXPERIMENTS IN THE USE OF NAPHTOL.

This remedy, a derivative of coal tar, which was introduced to the notice of the profession about two years ago by Kaposi of Vienna, has since been used in the treatment of various skin diseases. Kaposi's good results in the management of scabies, and to a lesser degree psoriasis, were confirmed by the writer; while although recommended very highly as a parasiticide and in the treatment of hyperidrosis, naphthol was not found to fulfill the promise made for it in these affections. Dr. Van Harlingen's experience found it of little value in the first and of no value in the second.

Dr. Fox said that he had used the drug extensively, and it did not give much satisfaction. It acted well in form of a lotion in some kinds of eczema of the scalp, also in eczema of the scrotum. In psoriasis of the face and scalp it failed altogether, and was not to be compared with the white precipitate ointment.

Dr. WIGGLESWORTH agreed with Dr. Fox, and did not believe that naphthol possessed any advantages over creosote, tar, carbolic acid, etc.

Dr. HARDAWAY found it of value in eczema fissurum of the hands.

Dr. TAYLOR used it in two cases of scabies with benefit; in cases of psoriasis it was found wanting.

LEPROSY.

The next paper, entitled *A Trip to Tracadie*, was read by Dr. FOX of New York.

The paper embraced a description of the hospital for lepers at Tracadie, New Brunswick, also the result of an examination of the cases of leprosy there seen. The conclusions, as presented by Drs. Fox and Graham, are as follows:—

- (1.) Leprosy is a constitutional disease, and in certain cases appears to be hereditary.
- (2.) It is undoubtedly contagious by inoculation.
- (3.) There is no reason for believing that it is transmitted in any other way.
- (4.) Under certain conditions a person may have leprosy and run no risk of transmitting the disease to others of the same household or community.
- (5.) It is not so liable to be transmitted to others as is syphilis in its early stages. There is no relation between the two diseases.
- (6.) Leprosy is usually a fatal disease, its average duration being from ten to fifteen years.
- (7.) In rare instances there is a tendency to recovery after the disease has existed for many years.
- (8.) There is no valid reason for pronouncing the disease incurable.
- (9.) Judicious treatment usually improves the condition of the patient, and often causes a disappearance of the symptoms.
- (10.) There is ground for the hope that an improved method of treatment will in time effect the cure of leprosy, or at least that it will arrest and control the disease.

The President suggested that the remarks should be confined to the following points: Clinical history, question of heredity, modes of contagion, duration, curability, treatment.

Dr. SIMMONS, of Japan, being present, was invited to take part in the discussion. This gentleman said that he had studied the disease for the last fifteen years. He claimed that it was difficult to study it in a hospital, where effect of climate, mode of life, etc., is not noticed. Among the first symptoms are a peculiar

lividity, blushing on least excitement, — then the anæsthetic spots. Its progress is often slow, extending over a period of years. He regarded the disease as hereditary, and spoke of the difficulty of obtaining a true history. It is the first question in marriage among the Japanese. He did not consider it contagious or infectious, and never had any fear of it. In Japan, when a man becomes the subject of the disease, he exiles himself, when a woman, she is put out of the way by her family. It occurs mostly among the wealthy, and in regard to treatment, the first thing is a thorough system of diet and hygiene. The best results are obtained with Gurjun oil, internally and externally.

Dr. ROHÉ thought that if leprosy spreads by contagion there must be a great difference as to the susceptibility on the part of individuals.

Dr. WIGGLESWORTH called attention to the fact that physicians and nurses are rarely if ever affected. He thought the disease was slightly contagious and feebly infectious.

Dr. GRAHAM believed in the contagiousness of the disease.

Dr. PIFFARD cited the case of Boileau, the physician of the island of Mauritius, as having had leprosy.

Dr. WIGGLESWORTH related a conversation which he had with Professor Boeck of Christiania, who had followed up the history of a Norwegian leper emigrating to America, and found that in one of the descendants in whom the disease had developed it seemed to have lost its virulence.

A paper was then read by Dr. SHERWELL, of Brooklyn, entitled, —

PAGET'S DISEASE, OR MALIGNANT PAPILLARY DERMATITIS.

The writer had found twenty-seven cases recorded. He reported two, the first one having been the first published in America. The description of the two cases was followed by the narration of some diagnostic points, for example, the burning, itching, and other subjective symptoms were more marked than in eczema. The "malignant papillary" feature was sufficient to resolve any doubts between it and true eczema.

AUGUST 30TH. MORNING SESSION.

A paper on the

PATHOGENESIS OF DRUG ERUPTIONS

was read by Dr. MORROW of New York.

The different theories as to the action of drugs in the causation of eruptions on the skin were given, and the writer inclined towards that theory according to which drugs produced some irritation of the central or peripheral vaso-motor centres.

The next paper, entitled, —

CHANGES OBSERVED IN THE NON-ULCERATING TUBERCULAR SYPHILIDE,

was read by Dr. TAYLOR of New York.

The writer cited a case which was kept under close observation for five months, and during that time a non-ulcerating tubercular syphilide was seen to undergo several changes. The lesions first became hypertrophic, then assumed a colloid nature like those in lupus. In some tubercles yellowish puncta appeared, which increased, coalesced, and looked like pemphigus syphiliticus.

DR. ATKINSON thought that the changes as observed by Dr. Taylor were evidence of the fact that syphilis may simulate all forms of cutaneous disease.

PSEUDO-PSORIASIS AND PSORIASIS OF THE PALM.

The next paper, entitled Pseudo-Psoriasis of the Palm, was read by DR. SHERWELL of Brooklyn.

The writer regarded psoriasis of the palm as the result of a concomitance, of a superimposed or congenitally double diathesis. He believed that the squamous eruptions on the palms (excluding eczema, etc.), resembling psoriasis, always had a specific diathesis for its base.

DR. ALEXANDER, of New York, read a paper entitled, Psoriasis Affecting the Palms.

The writer presented four cases of psoriasis of the palms, of a typical character, in all of which the most careful examination failed to show any sign of previous or existent syphilitic disease. Photographs of the cases were also exhibited.

DR. GRAHAM reported two cases of psoriasis of the palms with peculiar affection of the finger nail. There was no syphilitic taint.

DR. MORROW also reported cases without evidence of syphilis.

DR. TAYLOR said that he had seen three of the cases reported by Dr. Alexander, and could not upon the closest inquiry discover any traces of syphilis. He regarded psoriasis of the palms as beginning about the nails, and as probably of traumatic origin.

DR. SHERWELL still maintained his views, having seen cases of almost universal psoriasis without any lesion on the hands, then the patients acquiring syphilis, lesions would appear on the hands.

DR. ALEXANDER thought that the lesions on the palms may be evanescent and occur seldom on account of the friction to which the surface is subjected, this causing a rapid tissue change.

A paper was read by DR. WIGGLESWORTH for DR. HYDE, of Chicago, entitled, —

A STUDY OF THE COINCIDENCE OF SYPHILITIC AND NON-SYPHILITIC AFFECTIONS OF THE SKIN.

The writer discussed the coincidence of certain skin diseases with syphilis, dwelling particularly upon psoriasis, of which he offered two cases. Two patients affected with generalized psoriasis became syphilitic. Syphilitic eruptions followed, and under treatment gradually disappeared, the psoriatic lesion again appearing; the palms and soles were not invaded.

EVENING SESSION.

A paper was read by DR. TAYLOR, of New York, entitled, —

PECULIAR APPEARANCE OF THE INITIAL LESION OF SYPHILIS AT ITS BEGINNING.

Dr. Taylor presented two cases; in one the lesion was on the right lip of the meatus, in the other on the dorsum of the glans. The lesions were about the size of three pin heads, of a silvery, glistening appearance, non-elevated without fissures, and looked as if caused by application of nitrate of silver. The lesions remained superficial for two weeks, then developed into typical chancres.

A paper was read by DR. STELWAGON for DR. DUHRING, of Philadelphia, entitled, —

THE VALUE OF A LOTION OF SULPHIDE OF ZINC IN THE TREATMENT OF LUPUS ERYTHEMATOSUS.

The writer reported three cases which were obstinate and had resisted all modes of treatment; but the application of the following lotion was attended with marked benefit: —

R Zinc sulphate	{ ss 3i
Sulphuret of potash		
Water		q s iv.

DR. PIFFARD thought that to cure a lupus of any kind it must be destroyed, and this he claimed was best effected with the curette or by scarification. He doubted whether the remedy proposed would cure a case.

DR. ALEXANDER had practiced scarification sometimes with success, at other times aggravating the lesions. He doubted the efficacy of the remedy proposed by Dr. Duhring.

DR. SHERWELL used the remedy in acne, where it seemed to reduce the hyperæmia.

DR. VAN HARLINGEN saw one of the cases presented by Dr. Duhring, and could abundantly verify the claims as to the success of the lotion in that case.

DR. WIGGLESWORTH thought the disease was difficult to cure; he had, in several cases, used salicylic acid and chrysarobin, as advised by Dr. Fox.

DR. FOX said that he had used this combination with some success, but carbolic acid, pure, painted on the part, was in his experience the best remedy.

DR. PIFFARD thought the efficacy of a remedy in lupus erythematosus depended upon its ability to excite enough inflammation to strangle out the new cells.

DR. HARDAWAY claimed to have had success by electrolysis with a needle.

A paper was then read by DR. VAN HARLINGEN for DR. DUHRING, of Philadelphia, entitled Report of

A CASE OF AINNUM, WITH MICROSCOPICAL EXAMINATION.

The writer reported a case of ainnum occurring on the right little toe of a negro. The distal phalanx was removed by operation, and was exhibited. The clinical history of the case was followed by a full microscopical report prepared by Dr. Duhring's clinical assistant, Dr. Henry Wile.

DR. SHERWELL thought that the affection was a species of self-mutilation practiced by the lazy negro, — that it was probably akin to "ring toe."

DR. HARDAWAY reported five cases of

A PECULIAR PAPILLARY DISEASE OF THE SKIN,

in which the lesions were of a chronic type, of a peculiar lemon-yellow color, varying in size from a grain of wheat to a split pea, gave exit to a drop of blood on puncture, and had a pseudo-vesicular appearance. It disappeared promptly after the use of the following: —

R. Hydrarg. ammoniat.	{ ss 3i.
Liq. picis alk.		
Ung. petrol.		3i.

DR. WIGGLESWORTH thought the lesions described by Dr. Hardaway were new.

DR. ATKINSON recalled a case of a young negro woman who exhibited certain wart-like lesions on the cheek, which, being pricked, gave exit to a drop of blood.

DR. GRAHAM presented a case of

LYMPHANGIOMA CUTIS,

with photographs. The lesion consisted of a loose fold extending from the shoulder to the wrist of the right arm. The epidermis was much hypertrophied, was soft and velvety; near the elbow were deep furrows. Near the elbow was a large tumor, in which large dilated vessels were felt. The lesion could be reduced in size by compression or elevation of the part.

DR. ATKINSON said that he had a case similar to that of Dr. Graham. He thought the condition was one of densely infiltrated tissue, with enlarged lymphatics.

DR. PIFFARD suggested, in the matter of treatment, the galvano-caustic ligature.

DR. SHERWELL mentioned a case of lymphangioma cutis of a solidifying nature, where the lymphatics were indurated, so that the man could not sit down.

AUGUST 31ST. MORNING SESSION.

Microscopical specimens of malignant papillary dermatitis, also specimen of ainhum, were exhibited.

PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

SURGICAL SECTION.

H. C. HAVEN, M. D., SECRETARY.

MAY 16, 1883. Thirty members present. DR. J. P. REYNOLDS was elected chairman for the evening.

DR. A. N. BLODGETT read a paper entitled Dislocation of Sternal End of Clavicle and of First and Second Ribs at Sternal End.

DR. T. DWIGHT read a paper entitled, —

A NEW DEMONSTRATION OF THE CAVITIES OF THE MOUTH, NOSE, AND PHARYNX.¹

The paper was illustrated by a demonstration of the section according to the method described.

In the discussion which followed DR. CHEEVER said that the demonstration certainly gave a clearer idea of the proper relations of the parts than any other he was acquainted with, and he considered it of great value. Dr. Cheever had often been able to feel the arytenoid cartilages; in fact, often the projecting cornua of these cartilages are mistaken for foreign bodies. This mistake can be guarded against by recognizing that they are entirely covered over by mucous membrane; this is never the case with foreign bodies. Dr. Cheever spoke of the valuable information which can be often obtained by exploring the posterior nares with the finger. The relation of the parts as shown by Dr. Dwight's demonstration enforced the necessity of keeping the tongue well forward in case any obstruction to the passage of air existed during etherization. In connection with a remark concerning the relations of the tonsil, Dr. Cheever said he dissented from a statement made at a preceding section meeting, that abscess of the tonsil never causes death by suffocation. He had seen such a case.

DR. DE BLOIS spoke of a method of examination by which he had been able to remove a papillary growth from the vocal cords with the nail of his index

finger. The method consists in introducing the index finger between the cheek and the jaw until behind the last molar, and then going down. In this way the flexure between the first and second fingers comes against the angle of the mouth, which is pressed back, the other fingers lie on the outside of the cheek. Dr. De Blois thought he could gain half an inch in this way.

ABSENCE OF WATER FROM THE STOMACH AFTER IMMERSION OF A CORPSE.

DR. F. W. DRAPER called attention to the fact that the medico-legal point of water not being found in the stomach in cases where the body was put in the water after death was very easily understood if we considered the relations of the parts to be as the more recent diagrams showed us. According to the old ideas, however, according to which the oesophagus was an open tube, this absence of water would be inexplicable.

THE THIRD TONSIL AND DIPHTHERIA.

DR. BLODGETT spoke of the presence of the third tonsil as accounting for the readiness with which diphtheria attacks the posterior nares.

DR. D. W. CHEEVER was elected chairman for the ensuing year.

Recent Literature.

A New School Physiology. By RICHARD J. DUNGLISON, A. M., M. D., etc. 12mo. 314 pages. Philadelphia: Porter & Coates. (No date.)

This volume is intended for the instruction of children, and includes some practical hygiene. It is by no means abreast with the recent advances of physiology: witness the account of digestion, of absorption, of the functions of the cerebellum, etc., which all seem curiously antique. We also miss that vividness which comes from first-hand acquaintance with the facts described; for the volume appears to be a product of mere compilation, and not to be written with any expectation that the students shall see everything possible for themselves. As there are good books of this kind in which exist the qualities missed in Dr. Dunglison's school-book, we are unable to express a preference for the latter. It would have appeared very good ten or fifteen years ago, but fails to meet the requirements of to-day, since books alone no longer suffice for the teaching of natural science.

— A writer in the *Practitioner* says, in administering anæsthetics in excisions of the tongue it seems all-important that the anæsthesia should *not* be profound. He holds that partial insensibility only is admissible, and has seen more than one fatal case during removal of the tongue, the patient being profoundly insensible. He believes that if there be much or little bleeding, mop as much as you may, some blood trickles backwards, and little pools accumulate in the glosso-epiglottidean pouches, and flow over into the larynx, and the epiglottis, being held erect by the drawing forward of the tongue, cannot divert its course. On the other hand, the patient coughs up the blood if only *partially* under the anæsthetic.

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 13, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY, No. 4 PARK STREET, BOSTON, MASS.

ACUTE PNEUMONIA. A PRELIMINARY REPORT OF THE COLLECTIVE INVESTIGATION COMMITTEE.

AN abstract of the report of a sub-committee of the collective investigation committee of the British Medical Association on the communicability of phthisis was recently given in the JOURNAL. Another sub-committee, represented by Drs. Sturges and Sidney Coupland, has rendered a preliminary report on acute pneumonia, which contains figures of interest as adding to our statistical knowledge of this very common, and, from a physiologico-pathological point of view, somewhat puzzling disorder. This preliminary report is based upon an analysis of 350 cases returned in answer to cards sent out by the committee. These cases were analyzed under nine different headings:—

(1.) *Sex, Age, and Mortality.* Of the total number of cases 229 were males and 120 females, the sex in one case not being mentioned. The proportion of males to females was therefore nearly two to one.

As regards age two cases are given of infants under one year; from that age to ten years there are 43 cases. Between the ages of ten years and sixty years there fall 269 cases, of which number 195 occurred between ten and forty years, the greatest prevalence being between ten and twenty, and twenty and thirty, each of these decades yielding 70 cases. Nine cases are given between seventy and eighty years, and one over eighty, who recovered. In seven cases no age is stated.

The question of mortality is considered from various points of view, so as to ascertain, if possible, particular external or internal conditions influencing the course and termination of the disease. These are: (a) sex and age; (b) habits and mode of life; (c) sanitary conditions of the dwelling; (d) the type of pneumonia, as shown by its mode of onset; (e) the extent of the pulmonary inflammation.

Of the 350 cases 282 recovered and 68 died, giving a general percentage mortality of 19.4. (a.) The percentage mortality among the males, on the other hand, was 18.7, and among the females 20.8. In regard to the proportion of cases and the ratio of mortality between males and females, as well as to the influence of age upon mortality, the reporters realize perfectly that the figures are too small for any definite conclusion, and offer them only as a contribution. So far as the cases go the rate of mortality rises with

each decade of life from ten years to forty; between ten years and twenty the mortality was 7.1; between twenty and thirty 11.4 per cent.; between thirty and forty 18.1 per cent.; between forty and fifty years the mortality, instead of continuing below the general average, is more than doubled, namely, 40.4; between fifty and sixty 34.3 per cent.; above sixty years of age the cases reported were too few to infer anything as to rate. (b.) As to habits and mode of life, 228 are recorded as "temperate," 80 as "total abstainers," and 37 as "intemperate;" in 30 cases the food was said to be insufficient. In regard to the relative mortality of cases thus classified the reporters think if any conclusion can be justifiably drawn from their figures it is "that whereas individuals of temperate habits and those who take a sufficiency of food incur about an equal liability to fatal pneumonia the total abstainers enjoy a far greater immunity; whilst among the intemperate the death-rate is very high indeed. The figures are, however, too few to permit of such a deduction, except, perhaps, in the case of the intemperate, where the result is in accord with general experience. An insufficient supply of food, which in many cases goes along with alcoholic excess, does not, according to these results, seem to be so fatal a determining factor as the latter." (c.) The returns afford no evidence that insanitary surroundings form a main factor in the occurrence of a fatal type of pneumonia. (d.) Neither do they offer evidence that the type of pneumonia attended with a fatal issue differs from that of non-fatal cases. (e.) Of the 68 fatal cases one lung alone was involved in 37, namely:—

Right side, apex 1.	Base 17.	Apex and base 4.
Left side, apex 2.	Base 10.	Apex and base 3.

Both lungs were attacked in 31 cases, the signs being limited to the apices in one case, to the bases in 22. The whole of both lungs was affected in two cases; the whole of the left lung and right apex in two; left lung and right base in two; and right lung and left base in two.

(2.) *Sanitary and Meteorological Conditions.* This question the reporters regard as "a most difficult one, not, perhaps, to be determined by statistical results or by such facts as can alone be gathered by an inquiry like this." In one half of the 350 cases the sanitary condition of the houses in which the patients lived was reported as "indifferent" or "bad;" and one half of the districts in which pneumonia was reported to be prevalent were said to be "indifferent" or "bad" in sanitary respects. In only about one third of the cases was the sanitary state "good" as regards both house and district. The reporters conclude that, "although it would thus appear that insanitary conditions play a not inconsiderable part in the aetiology of pneumonia, it is impossible to question the fact that marked influence is exercised by special meteorological states. Without venturing to assert in what this influence precisely consists, we think that few would deny that the state of the atmosphere as regards barometric pressure, humidity, temperature, and direction of the wind, does operate in exciting or favoring the development of this disease. . . .

"Reserving the full analysis of the weather conditions registered in these 350 cases, we may state in general terms that more than one half of the total number of cases arose when the weather was damp or wet, and even a larger number when it was cold, the combination of cold and wet being particularly favorable for the development of the disease."

(3.) *Specific Infectious Diseases Prevalent along with Pneumonia.* The result of this inquiry tends to negative the belief in any direct or intimate connection between pneumonia and any of several specific or infectious affections, — such as enteric fever, diphtheria, tonsillitis, erysipelas, etc., — which are apt to prevail coincidentally with it.

(4.) *Family and Personal Histories.* The material analyzed by the reporters teaches, as far as it goes, that individuals who become subjects of pneumonia do not exhibit in excess any particular morbid predisposition; that the liability to this disease is not transmitted; that one attack of pneumonia does render an individual rather more liable to a second attack. Thirty cases of recurrence are reported out of 350. There was a phthisical family history in but 34 of the 350 cases reviewed. The common rule in the cases reported and surviving, with very few exceptions, was complete recovery without sequelæ.

(5.) *Mode of Onset.* The following is a numerical analysis of the differences in the modes of onset: —

"Premonitory symptoms were present in about 270 cases.	
Premonitory symptoms were absent in about 80 cases.	
Rigor occurred at the onset in	241 cases.
Rigor was not present at the onset in	39 cases.
Cutarrhal symptoms preceded the attack in	40 cases.
Cough symptoms preceded the attack in	29 cases.
Headache symptoms preceded the attack in	53 cases.
Malaise symptoms preceded the attack in	49 cases.
Erysipelas symptoms preceded the attack in	1 case.

"The total number of cases in which *gastro-intestinal* symptoms were present was 59; in seven of these after the onset of the pneumonia. Of these symptoms, nausea and vomiting occurred in 35; in 21 of which a rigor ushered in the declared symptoms. Diarrhœa was the only symptom in 13 cases (in one, No. 71, with hæmorrhage); a rigor occurring in eight. Vomiting and diarrhœa existed together in but three cases, in one of which there was a rigor. Thirteen of these cases were fatal, or 22 per cent. of the number so attacked, a figure somewhat above the average mortality."

(6.) *Seat of Lung Inflammation, Days of Crisis, etc.* In regard to the seat of lung inflammation we quote the words of the report: "(a.) The situation of the lung inflammation is a point of interest in reference to the proportion of cases of double pneumonia, and of so-called apex pneumonia; as well as to the comparative frequency with which this or that locality of the lung becomes the seat of attack. The general belief in the greater frequency of *right* pneumonia is here borne out by 108 cases in which the right base was affected against 86 of the left base; and 16 of the right apex against 10 of the left. That the inflammation should have been confined to one or other apex in but 26 cases out of the whole number is re-

markable. We venture to think (and are supported in this belief by the present returns), that 'apex pneumonia' is apt to occur in groups at certain times and seasons, and that ultimately the above proportion will be found to be below the average.

"In one instance, a fatal case, verified by post mortem, both apices are affected, a solitary example which calls attention to the extreme rarity of pneumonia of this seat, and contrasts strikingly with 76 cases where both bases are involved. Next in rarity is the implication of both bases along with one apex. This combination occurs in but five cases as regards the left apex, and in but three as regards the right apex. By far the commonest seat is the right base.

"In 334 cases the numbers are: Right base, 108; left base, 86; both bases, 76; right apex, 16; left apex, 10; right base and apex, 12; left base and apex, eight; both bases and right apex, three; both bases and left apex, five; whole of right, three; whole of left, four; 'whole of both lungs,' two; middle lobe, one."

(b.) A comparison of the number of cases ending suddenly with those that had a gradual subsidence gives 138 of the former to 168 of the latter, "in other words, the crisis of acute pneumonia, to which many attach importance as among the indications of the specific character of the pneumonic fever, is more often absent than present." (c.) The days of crisis are generally supposed to fall, when they manifest themselves, somewhere between the third and the eighth day. Out of 290 cases 65 had their crisis on the seventh, and 43 on the sixth day, while the number ending in crisis on the eighth day are but 29, less than half those on the seventh. Crisis later than the eighth day is very exceptional. It is in this series more frequent on the tenth than on the ninth day (29 to 19). There are but seven instances of crisis on the eleventh day, and but two at any later period.

(7.) *Communicability of Pneumonia.* Twelve returns were received, supposed to be illustrations of the conveyance of pneumonia from person to person, but their analysis is reserved.

(8.) *Epidemic Pneumonia.* The returns received under this head are interesting as far as they go, but rather ambiguous.

(9.) *Treatment.* As between the restorative and stimulant, and the depressant or sedative treatments, the committee's returns show a strong preference in favor of the former, the number of cases treated on the former plan being five times as many as those treated on the latter. Antipyretic drugs — quinine in 61 cases, aconite in 51, digitalis in 25, the salicylates in 14 — were resorted to somewhat generally; the cold bath not at all, and we believe very properly, for it has shown itself least safe in pneumonia; cold sponging in five cases; and the wet pack in two; venesection is reported in only one case.

In conclusion the reporters state that within a year they expect to have at their command for analysis at least 1000 cases of pneumonia, a number sufficiently large, they think, to serve to set at rest many of the questions regarding pneumonia which are at present problematical. A final and detailed report will event-

ually be published. While desiring, therefore, to avoid any statement seeming to imply a final opinion upon their present material, they feel justified in saying that "the evidence as yet collected does not suffice to warrant the conclusion that the so-called acute croupous pneumonia is of specific origin."

THE ADAMS NERVINE ASYLUM.

THE sixth annual report of the Adams Nervine Asylum particularly attracts our attention, in part because it is the first report of that institution which has made its appearance on the editorial table, — it is only the second report which has been printed for distribution, — but more particularly because the institution itself is somewhat peculiar and exceptional in its character, and does its work so unobtrusively that little is known of its workings.

The report contains very accurate and abundant information in regard to the asylum, which was established in accordance with the will of the late Seth Adams "for the benefit of such indigent, debilitated, nervous people, who are not insane, inhabitants of the Commonwealth of Massachusetts, as may be in need of the benefit of a curative institution." Patients were first received in February, 1880, in the dwelling house on the estate, near the Bussey Institution, in Jamaica Plain, purchased by the asylum, and the new building specially erected for the purpose was first used in December, 1880. Rooms are provided for about thirty patients, and only female patients are received at present.

The number of patients under treatment during the year has been 105; of these seventy-six were admitted during that period. Their average stay in hospital was three and seven tenths months. Of the thirty-seven discharged as recovered the average length of treatment was about four and one third months.

The applications for admission reach the astonishing number of 371, which the superintendent considers a fair indication of what the future demands on the resources of the asylum are likely to be. He does not believe that it in any way indicates an increase of nervous disorders among women, but that it affords evidence of the urgent need felt for special facilities in the treatment of nervous derangements, and especially for such facilities as are afforded in this asylum.

Though no specific plans are mentioned for the increase in the accommodations it seems a fair inference that a gradual enlargement is contemplated, as after some changes in the grounds during the past year the asylum now owns seventeen and a fraction acres, and has erected during the past year a special building for the use of the nurses, which contains twelve chambers, with sleeping rooms in the basement for other employees. The possession of this building is evidently a matter of great satisfaction to the management, as the want of similar accommodations is a matter of discomfort at other institutions. "By means of it," to

quote the report, "our nurses are now enabled to obtain that relief from the exacting cares and depressing influences of their vocation which their health and comfort demand."

Several very interesting tables are given showing the various conditions and relations of the patients, but no special deductions are drawn from them, perhaps because the numbers are too small. These tables show that of the seventy-six females admitted for treatment forty were unmarried, twenty-seven were housewives or housekeepers, nine were teachers, and twenty-six were of no occupation. No tabulation of distinct diseases is given, but the following observations on treatment are instructive, and sufficiently interesting to give entire: —

"The value of 'rest and seclusion' as remedial agents is an exceedingly interesting question in view of the rather indiscriminate application which has been made of this treatment to all forms of nervous disturbance whether of cerebral, spinal, or peripheral origin. This method of treatment is of great value in many disorders, the characteristics of which were mentioned in last year's report. In hysteria it assists by its discipline in regaining self-control, but *not* in melancholia, either of a mild or severe type. On the contrary, its use in cases of *depression* invariably aggravates rather than soothes or mitigates the symptoms, and I do not resort to it in the treatment of this class of patients. In nervous exhaustion, so called, whether of cerebral, spinal, or mixed types, it is more certain of satisfactory results than any other plan yet tried. It retards waste, checks morbid activities, and prevents the drains and lesser strains so fruitful in perpetuating this condition. Whether imaginary or real, the confused thought, the supposed loss of memory or its sudden lapses, the weaknesses of vision, the irregular and varied forms of circulatory disturbances, the disturbed digestion, the motor irregularities, incapacity for work, insomnia, and all other symptoms, speedily disappear under its judicious use seldom to reappear."

Dr. Page's ideas on this subject are given at length in this journal, vol. cvii., p. 77.

In reference to the stability of the cures, Dr. Page says: "As the asylum is comparatively new, having been in practical operation less than four years, and therefore not rich in experience, it is impossible to base upon its results conclusive or reliable deductions. In general, however, it may be stated that heredity and temperament exert an important influence in determining this question. It is well known that heredity carries with it from one generation to another abnormal anatomical peculiarities, as, for instance, supernumerary fingers and toes. So neurotic traits, whether psychological or not, to a much greater degree manifest themselves in parents and children for successive generations. Even disturbed nerve functions, like migraine and neuralgia, perpetuate themselves in different members of a family through a long line of descent. Always quiescent in good health, these neuroses promptly manifest themselves whenever nutrition is seriously disturbed."

MEDICAL NOTES.

—Malarial diseases are reported by the secretary of the Connecticut Board of Health, as unusually prevalent in places like Manchester, where they have more recently appeared, while in the places where they first appeared but little prevalence is noted, and the deaths from typhoid fever exceed those from all forms of malarial fever. Still, even in these places, there has been quite a number of cases of acute intermittent fever, which has not been noticeable before for several years. Upon the whole, however, the malarial influence appears to be waning very decidedly and its effect upon other types of disease less marked. The sale of quinine at the drug stores has rather decreased in comparison with that of former years. The progress into new territory is slow; but few towns report cases. Hampton, in Windham County, reports a few cases. This is one of the hill towns with little swampy land comparatively. Several cases are reported from Watertown, Naugatuck, Monroe, Had-dam, Suffield, Windham, and Westport, but in general malarial diseases occupy a much less prominent place, while typhoid fever is increasing in frequency.

—“*A Good Plan.* — £10 and upwards judiciously invested in Options on Stocks and Shares often give handsome profits in a few days. Full details in *Explanatory Book gratis and post free,*” etc. This advertisement from one of the best of the English medical journals is a kind of announcement which, with all the “enterprise” of American medical publishers, we do not remember to have seen in any of our professional periodicals. Can it be possible that American doctors are too old birds for the fowlers to waste their chaff upon?

—It is said that in a recent suit for divorce in Ohio an interesting pathological question was raised. It was claimed that a fibroid polypus of the uterus was developed by the conduct of a man in courting a woman. Long courting, causing the woman to think of her speedy entering upon the duties of a wife and mother, produced such disorder in and about the uterus as to cause the growth of the tumor.

NEW YORK.

—Typhoid fever seems to be on the increase, an unusually large number of cases having been reported since the 1st of September. Between the first and seventh of the month there were over sixty cases registered, and twenty-five deaths from the disease.

—Dr. James Dowling Trask, a distinguished practitioner of Astoria, Long Island, died on the second of September. He was born in Beverly, Mass., in 1821, and was a graduate in arts of Amherst College. He received the degree of M. D. from the University of the City of New York in 1844, and subsequently the honorary degree of M. D. was conferred on him by the Medical College of Buffalo, N. Y. He was professor of obstetrics at the Long Island College Hospital for a number of years, and throughout his professional career made many valuable contributions to medical literature, principally in the field of midwifery and gynecology. Among them was an

essay on *placenta prævia*, embodying researches and statistics of permanent value, which received the prize of the American Medical Association in 1855.

—Dr. Charles Wright, senior medical examiner of the New York Life Insurance Company, died in London, Eng., September 2d, of congestion of the lungs resulting from Bright's disease. Dr. Wright was graduated from the Medical Department of the University of New York in 1853, and after a few years spent in general practice was appointed, in 1862, assistant medical examiner of the above insurance company. Upon the death of the late Dr. Wilks, in 1876, he was made a medical director of the company. At the time of his death he was treasurer of the board of trustees of the New York Academy of Medicine, and he was universally respected in the profession.

—A physician, who kept a drug store at Alleghany, New York, recently made the mistake of putting up for a patient five grains of morphia powders instead of quinine, and the man having died from the effects of one of them, he was so overcome with grief on hearing of the catastrophe that he committed suicide by taking morphia himself.

Correspondence.

SHRINKAGE IN CIRRHOSIS OF THE LIVER.

MR. EDITOR, — I should like to learn from some of your numerous readers in how short a time, in a case of cirrhosis of the liver, shrinking may take place. I saw in consultation, the 21st of June, a lawyer, forty-two years, a hard drinker, whom both the attendant and myself regarded as having cirrhosis of the liver in the enlarged stage. Heart and lungs sound. The liver extended in the mammary line from the sixth intercostal space to the umbilicus, and was both tender to touch and rough on surface and edge. Although the patient's father had died of cancer of the stomach, we thought cirrhosis would account for all the symptoms, even the coffee-ground vomitus. I saw him again July 18th, and there was no marked change, save the liver was a third smaller; there was no ascites, and no tumor in epigastrium. On August 16th I again saw him, when I found him much weaker; pulse feeble; face haggard; eyes jaundiced; slight emaciation; still tenderness over liver and in epigastrium; no marked pain; some ascites. At this time the liver dullness was not over two fingers' breadth in the mammary line. Just before my visit the patient had vomited up a chamber vessel full of coffee-ground blood. We still thought it a case of simple cirrhosis, though we did not overlook the possibility of cancer of stomach also. The next morning the patient died, and I made the same afternoon the autopsy.

Only abdomen opened. There was no ulceration or infiltration of stomach, which, with intestines, was full of coffee-ground blood. The liver was one third normal size, deep yellow in color, dense, and covered with nodules from size of pin's head to pea; on section it cut with a creaking sound, and offered considerable resistance to knife. The kidneys were fatty and enlarged. Unfortunately, I did not lay open the whole duodenum.

I have inquired of several of my professional friends

regarding the time requisite for the shrinking, and they seemed to think it a very slow process; books seem to give no data for an opinion. In this case between the 20th of June and the 16th of August the liver had shrunk from between seven and eight inches to less than two as measured in the mammary line. Specimens for histological examination were not to be had.

Very sincerely yours,

WILLIAM WOTKYNs SEYMOUR, M. D.

TROY, N. Y., September 5, 1883.

IODOFORM ABSORPTION AND INSANITY.

MR. EDITOR.—The case of pemphigus pruriginosus, as reported in your journal¹ by Dr. G. M. Garland, I read with a great deal of interest, so much the more as the result of the treatment with iodoform in a disease so little amenable to treatment was all that could be desired. Dr. Garland dwells with right on the mental disturbances accompanying the treatment. Will he allow me to ask him whether he would not think it possible that this mental disorder originated from the effect of the absorbed iodoform applied to two hundred and eighty ulcers? and most satisfactory as the local application of the drug turned out to be, whether we have not an iodoform poisoning to deal with, the result of which was insanity in the case?

If I am right, mental disorders belong to the train of symptoms in iodoform poisoning.

Very respectfully yours,

GUSTAVE LIEBMANN, M. D.

467 COLUMBUS AVENUE, BOSTON, MASS.

Miscellany.

EDUCATION IN THE MEDICAL PROFESSION.

MR. EDITOR.—There is certainly no excuse at the present day for the lamentable ignorance of physicians who hold diplomas from reputable medical institutions. Two courses of lectures, apart from any preliminary examination upon matriculation, seem to satisfy the large majority of students, and at a time, too, when they possess advantages far above the physician of half a century ago. With but one or two exceptions no entrance examination is required by medical schools of those applying for admission, and the college graduate is placed upon a par with those hardly possessing a knowledge of the first elements of a sound English education. Look at any catalogue of a medical school, and we will find that hardly more than ten or twelve per cent. of those whose names appear in its pages are college or academical graduates. Every day the percentage of students increases, but not an increase of those who can claim any great educational acquirements. So instead of the medical profession keeping pace with the culture of the times, it has scarcely reached the high-water mark of the old-time physician, who made use of every means which paved the way to success and eminence.

Instead of struggling with questions of codes and ethics (and this chiefly among those whose lack of preliminary culture peculiarly unfits them for entering upon the discussion at all) the modern physician should be made to see the necessity of a wide and liberal

culture ere entering upon so important a vocation as the practice of medicine. Hence no encouragement should be given those who are without this preparation, for a physician who has passed his prime has neither the time nor the inclination to remedy the defects in his early education, nor the discipline which such study always confers upon him.

The Massachusetts State Medical Society has for some years past insisted upon a preliminary examination of every candidate who applies for fellowship. This consists not only in the English and Latin languages, but also in his knowledge of his profession. The Rhode Island Society has now adopted a like practice, whereby it is hoped all applicants will be subjected to a system of "sifting," and thus be preserved the honor of the Society. In two State societies, at least, the simple possession of a diploma is no longer an index of the owner's fitness to practice medicine.

Medical schools can do much to aid State societies in this work. Harvard, Yale, and the University of Pennsylvania require entrance examinations of all students who propose to commence the study of medicine. Other schools do not as yet even insist upon attendance upon *three full courses of lectures* before the student is allowed to graduate. As a consequence the country is flooded with hosts of unqualified physicians, their diplomas being merely vouchers of their unqualifications.

But so long as the money question forms so large a factor in the medical curriculum we fear that the time will be far distant when its influence will cease to bias all attempts at reform. So long as State legislatures continue to incorporate medical schools of little or no merit, with teachers who take this cheap way of advertising their indifferent skill, the educated physician must still become a dream of the future. Such a practitioner scarcely ever learns the art of study; never studies long enough to master the first principles of his profession. He knows just enough to pass "muster," to pass an examination which it is for the interest of the examiner to make as easy as possible. Hence the greater the number of graduates the larger the amount of money at his command, especially in the future, for students flock to those institutions where the requirements are the least, and the expenses smallest, a medical education being measured in dollars and cents and the brevity of the course of instruction. And yet it is not so much the fault of the student as the teachers. Temptations are continually held out to an unthinking class which they cannot in the nature of things overcome.

A last method of cure lies in the practitioner himself. He should refuse to instruct pupils unless they are possessed of a fair education, an education which only academies of high order and colleges can give. If honest attention be given to this subject legalized charlatanism will no longer be a disgrace to the profession, nor shall we hear longer of half-caste physicians, and an overcrowded profession. The worse elements will all be carefully weeded out, the profession of medicine attain an eminence far beyond the reach of the sneers of the laity. Only in this way may the medical profession redeem its honor, and hold its place among the learned professions, for, if the truth must be told, it is to-day far, very far, from occupying the enviable position which it might.

Yours,

F. C. CLARK.

9 THOMAS STREET, PROVIDENCE, R. I.

¹ No. 8, volume cix.

SOME POINTS REGARDING THE USE OF BROMIDES IN EPILEPSY.

In a lecture by Professor Dujardin-Beaumetz (*Medical Record*, August 25th) on the treatment of epilepsy, we find some hints regarding the form and method of administration of the bromides in this disease. In answer to the question, what is the active principle in the bromides, the bromine or the base, the author replies:—

"The bromide plays a considerable part in this depression of the bulbar functions, but the base does not by any means remain inactive or inert. And this it is which explains the difference of action of the different bromides. We know, especially since the labors of Laborde, that the salts of potash have a much more marked depressant action than the salts of soda, and that they have a toxic effect on the heart in particular. Already, when treating of purgatives, I showed you the difference which exists between the salts of potash and of soda; there is the same difference between chlorate of potash and chlorate of soda, as Laborde has shown; also between bromide of potassium and bromide of sodium, the first being more active than the second, while on the other hand the sodium salt is better tolerated than the potassium salt.

"I have made many trials of bromide of sodium in epilepsy, and notwithstanding the considerable doses exhibited, ten to twelve grammes (150 to 180 grains) a day, I have never succeeded in arresting attacks either of petit-mal or grand-mal by this salt. I have, therefore, been astonished to see in Hammond's remarkable work on Nervous Diseases that this eminent neuropathologist gives the preference to bromide of sodium in epilepsy.

"By the side of bromide of potassium we must place bromide of ammonium, which has a still more powerful action than the first; then bromide of calcium, with which I have never experimented, but which is much employed in America, and especially by Hammond. The latter, while giving the preference to bromide of sodium, considers bromide of calcium superior to the potassium salt; one gramme producing a sleep which is calm and refreshing. His vehicle of administration of the calcium preparation is syrup of the lactophosphate of lime.

"I have enumerated the alkaline bromides, of which the most employed is assuredly bromide of potassium. These bromides are often associated in prescription, a mode of administration called the *mixed bromides*.

"There are other bromide compounds which are sometimes given, as the bromide of zinc and bromide of camphor. Theoretically, the zinc bromide should be a good preparation, since zinc oxide possesses anti-epileptic properties, as we have before seen. Bromide of zinc is used in England and America in the form of a syrup. Hammond speaks highly of this salt in epilepsy.

"Introduced into therapeutics by Deneffe, of Brussels, and investigated chemically by Clin, therapeutically by Bourneville, bromide of camphor has been employed in the treatment of hysteria and epilepsy, and although favorable results have been obtained at the Salpêtrière, yet this preparation has not come into general use. Thus far the bromide of potassium remains the medicament, the most active and most employed in the treatment of epilepsy.

"The quantity of bromide which ought to be admin-

istered daily is very variable. From twelve to fifteen grammes a day have been given; the medium dose, in the majority of cases, is eight grammes. This dose cannot be given from the first; you must begin with smaller doses, as one gramme morning and evening, and gradually increase the dose till you have obtained complete control of the disease. Voisin thinks that we should regard as the maximum dose that which determines abolition of the reflex sensibility of the pharynx. I believe that this is an excellent rule in the case of hysteria, but not in epilepsy, and that in this disease we must not only attain abolition of pharyngeal reflex irritability, but we must, if occasion demand, push the administration of the remedy even farther, till we have stopped the attacks. But it is absolutely necessary to have a bromide preparation which is chemically pure, for Voisin has shown that the impurities of this salt considerably modify the therapeutical effects which it produces."

The writer considers that bromism, uncomfortable and even dangerous as that condition is, is to be accepted as preferable to the disease for which it is administered, especially in the delirium of action, which makes the epileptic a criminal without his knowing it, and when it is necessary to employ the bromide in massive doses in order to overcome the mania which impels him, unconsciously, to deeds of violence. Nothing, in fact, is more curious than to see in the wards of our lunatic asylums men enjoying their intelligence and their reason who have committed, and would still commit, the most astounding murders if their maniacal propensities were not kept in check day by day by immense doses of bromide.

How long should you continue the bromide treatment of epilepsy? Often a very long time, and even during the entire life of the patient. When, moreover, you have obtained the full benefit of the drug, and have witnessed complete cessation of the attacks, you must not leave off abruptly the medicine, but must keep on with it for several years, gradually diminishing the dose, as Legrand du Saulle has advised.

IRON AND ARSENIC IN ANÆMIA AND CHLOROSIS.

A PAPER in the *Practitioner* (July and August, 1883), by Dr. Willcocks, presents an interesting clinical and pathological study of the blood in these diseases, illustrated by a large number of cases. He is led to the following among other conclusions:—

In severe anæmia either the power of corpuscle formation is almost entirely abolished or young corpuscles, if formed, have little or no power to absorb hæmoglobin, and consequently do not reach their full development. The comparatively large size which the hæmatoblasts attain without the absorption of any appreciable quantity of coloring matter would go far to show that the embryonic corpuscles are more or less abortive. Iron in these cases is useless beyond a certain point, the existing corpuscles being already overcharged with hæmoglobin. These facts forcibly bear out the hypothesis enunciated at an earlier page as to the probable hæmatinic action of iron, namely, that it possesses no power of directly stimulating the formation of new corpuscles by any influence on the cytogenic organs, but that it improves the hæmoglobin

richness of already existing corpuscles, which are added to the blood by the normal processes, and consequently by improving their physiological value and vitality it indirectly increases their number. Therefore in cases like those under consideration, where the natural power of sanguification is greatly reduced, or almost abolished, iron has little or no beneficial effect, since either very few new forms are produced, or even if they are added to the blood they have little or no capacity to absorb hæmoglobin and to develop into adult corpuscles.

Chlorosis is in striking contrast to the most severe forms of anæmia both as regards its blood lesion and its response to iron treatment. In chlorosis the supply of young, feebly-colored corpuscles is abundant, and the number of red disks per cubic millimetre may fall in many cases but slightly below normal. The average hæmoglobin richness per corpuscle is greatly reduced, and the curative effect of iron is very rapid. A low average hæmoglobin value per corpuscle is not, however, peculiar to chlorosis, but is present in the large majority of anæmic cases from all causes. It indicates that feebly colored or young elements are being continually added to the blood, or, in other words, that the normal process of globule regeneration is active, the numerical rise preceding the rise in the physiological value of the elements. It is in these cases that iron is indicated. Arsenic was given in two cases of chlorosis, but it had no influence either in preventing relapse on the cessation of iron or in improving the number or value of the red corpuscles (Case I. and Case IV.). On the other hand, in the most intense forms of anæmia, with great diminution in the number of the corpuscles, and a high relative hæmoglobin value, iron is practically useless, or even harmful, while arsenic, as we see in the case of Caroline F., may produce a considerable rise in the number of the corpuscles, as well as great improvement in the general symptoms.

HYPERIDROSIS MANUUM.

MR. H. A. SMITH writes, in the *British Medical Journal*, concerning this affection, which occasions some ladies such heavy gloves' bills: Moisture of the hands (local hyperidrosis) is a purely functional disorder of the skin, due to disturbances of the nervous system. Stout women, generally servant girls, suffer from it, although the fair votaries of the ball-room and members of good society, together with those of lithe and nervous habit, occasionally come under notice. It may or may not be attended with pain and inflammation, dysidrosis or fetor-osmidrosis, or, more rarely, pigment-chromidrosis. As a rule, the axilla and feet sympathize more or less. As the condition appears to be due partly to abnormal vascular conditions, but mostly to irritability or undue stimulation of the vaso-motor nerves, probably of central origin, the following lotion will be found exceedingly useful:—

R Liq. plumbi subacetatis 3ij.
 Sp. vini methylati 3i.
 Aqua roseæ ad 3x.
 Fiat lotio.

The lotion to dry on, and the hands subsequently to be dusted three times daily with powder composed of equal parts of calamine and starch powders. The patient should wash the hands always in cold water, and well dry them, and should avoid malt and all fermented liquors, pickles, spices, tea, and coffee (taking cocoa),

and be sparing in the use of sugar. The lotion failing, she should wash the hands thrice daily with carbolic acid soap in soft water, in which half a drachm of extract of belladonna has been previously dissolved, and take a pill containing valerianate of zinc, two grains; quinine, one and one half grain; and extract of belladonna one fourth grain, with conf. rose q. s. t. d. s. A mixture (if any tingling or burning in the fingers) containing bromide of potassium, digitalis, and a vegetable tonic will complete the treatment. The belladonna, besides causing vaso-motor paralysis, contracts the unstriated muscular fibres surrounding the arterioles going to supply the sweat gland, and carbolic acid has a benumbing effect on the nervous filaments supplying these and the papillæ of the skin proper.

CONTROLLING HÆMORRHAGE IN AMPUTATION AT THE HIP-JOINT.

MR. JORDAN LLOYD describes in the *Lancet* (May 26th) a new method which he has several times employed for controlling hæmorrhage in amputations and excisions at the hip-joint. It is an adaptation of Esmarch's method. The limb is first elevated and stripped of blood. A strip of black India-rubber bandage about two yards long is then doubled and passed between the thighs, its centre lying between the tuber ischii of the side to be operated on and the anus. A common calico thigh roller must next be laid lengthways over the external iliac artery. The ends of the rubber are now to be firmly and steadily drawn in a direction upward and outward, one in front and one behind, to a point above the centre of the iliac crest of the same side. They must be pulled tight enough to check pulsation in the femoral artery. The front part of the band passing across the compress occludes the external iliac and runs parallel to and above Poupart's ligament. The back half of the band runs across the great sacro-sciatic notch, and, by compressing the vessels passing through it, prevents bleeding from the branches of the internal iliac artery. The ends of the bandage thus tightened must be held by the hand of an assistant placed just above the centre of the iliac crest, the back of the hand being against the surface of the patient's body. It is a good plan to pass the elastic over a slip of wood held in the palm of the hand, so as to diminish the pain attending the prolonged pressure of the rubber bandage. In this way an elastic tourniquet is made to encircle one of the innominate bones, checking the whole blood-supply to the lower extremity. The elastic bandage may be secured above the iliac crest in the usual manner with tapes, and may be prevented from slipping downward by being held with a common roller tied securely over the opposite shoulder. Experience has shown, however, that no mechanical means answer so well as the hand of a trusty assistant. When the band is once properly adjusted the assistant has only to take care that it does not slip away from the compress or over the tuber ischii. The former is prevented by securing pad and tourniquet together with a stout safety pin, and the latter by keeping the securing hand well above the iliac crest, or even more safely by looping a tape beneath the elastic near the tuber ischii, passing it behind under the sacrum and having it held in that position. The solid rubber tourniquet may be used instead of this bandage. I prefer, however, the bandage. The soft parts are less

damaged by reason of its greater breadth, and it is less likely to roll off the compress placed over the external iliac.

The ligature, being altogether above the limb, is out of the way of the surgeon in any operation at or about the hip-joint. The great trochanter is fully exposed, the hip being free upward as far as the iliac crest, and inward to the perinæum.

The bandage has the following advantages over Davy's lever: (1.) The simplicity and certainty of its application; no previous experience being necessary to compress the vessels, there is no possibility of going

wrong. (2.) The security with which the vessels are controlled, regardless of the movements of the patient or manipulations of the operator. (3.) The freedom from danger of injury to the rectum or abdominal contents. (Davy related a case at a recent meeting of the London Clinical Society in which he himself had wounded the rectum with his lever, the patient dying on the following day of peritonitis.) (4.) Its applicability to cases in which the rectal lever could not be employed, as in strictures of the bowel, intra-pelvic growths, and arterial abnormalities. (5.) It requires no special apparatus.

REPORTED MORTALITY FOR THE WEEK ENDING SEPTEMBER 1, 1883.

Cities.	Population by Census of 1880.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 2756 (no report from Buffalo): under five years of age, 1276: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 851, diarrhoeal diseases 467, consumption 322, lung diseases 145, diphtheria and croup 123, typhoid fever 71, scarlet fever 52, malarial fevers 47, whooping-cough 33, small-pox 20, cerebro-spinal meningitis 19, measles eight, puerperal fever six, erysipelas five. From *scarlet fever*, Philadelphia 10, Baltimore nine, Chicago eight, Brooklyn six, New York five, Boston and St. Louis three each, Pittsburg and New Haven two each, Cincinnati, District of Columbia, Milwaukee, and Charleston one each. From *malarial fevers*, New Orleans 11, New York and St. Louis 10 each, Brooklyn five, Philadelphia and Baltimore four each, Chicago three. From *whooping-cough*, New York 10, Philadelphia six, Brooklyn and Chicago four each, Baltimore, Cincinnati, District of Columbia, and Pittsburg two each, Milwaukee one. From

small-pox, New Orleans 17, Philadelphia three. From *cerebro-spinal meningitis*, New York five, Chicago two, St. Louis, Baltimore, Cincinnati, Pittsburg, Milwaukee, Lowell, Worcester, Springfield, Somerville, Chelsea, Taunton, and Haverhill one each. From *measles*, New York three, New Haven two, Chicago, Baltimore, and Providence one each. From *puerperal fever*, Chicago and St. Louis two each, New Haven and Fall River one each. From *erysipelas*, Philadelphia two, St. Louis, Cincinnati, and New Orleans one each.

Two cases of small-pox were reported in St. Louis; typhoid fever 45, scarlet fever 15, diphtheria six, measles one in Boston; diphtheria five, and scarlet fever three in Milwaukee.

In 37 cities and towns of Massachusetts, with an estimated population of 1,127,693 (estimated population of the State 1,922,530), the total death-rate for the week was 22.96 against 25.57 and 25.72 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending August 18th the death-rate was 20.2. Deaths reported 3342: diarrhoea 343, acute diseases of the respiratory organs (London) 178, measles 117, scarlet fever 99, whooping-cough 58, fever 44, diphtheria 17, small-pox (Birmingham, and Liverpool three each, London and Sunderland two each, Wolverhampton one) 11. The death-rates ranged from 12.4 in Halifax to 27.2 in Liverpool; Bristol 15; Bradford 17.1; Birmingham 18.1; Brighton 18.3; London 19; Plymouth 20.2; Leicester 21.4; Leeds 21.6; Sheffield 22.1; Nottingham 23.3; Newcastle-on-Tyne 23.7; Manchester 26.1. In Edinburgh 19.7; Glasgow 22.3; Dublin 24.9.

For the week ending August 11th, in 169 German cities and towns, with an estimated population of 8,690,485, the death-rate was 24.3. Deaths reported 4058; under five years of age,

2208; consumption 498, diarrhoeal diseases 383, lung diseases 286, diphtheria and croup 127, typhoid fever 72, measles and röteln 64, scarlet fever 64, whooping-cough 40, puerperal fever 18. The death-rates ranged from 12.1 in Erfurt to 33.6 in Görlitz; Königsberg 23.9; Breslau 28.5; Munich 36.4; Dresden 23.8; Berlin 28.9; Leipzig 21.7; Hamburg 19.8; Cologne 24.5; Frankfurt a. M. 16; Strasburg 23.9.

For the week ending August 18th, in the Swiss towns, there were 32 deaths from consumption, diarrhoeal diseases 24, lung diseases 12, scarlet fever five, whooping-cough five, measles four, diphtheria and croup four, typhoid fever three. The death-rates were at Geneva 12.3, Zurich 16, Basle 15.9; Berne 26.

The meteorological record for the week ending September 1st, in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

Date.	Barom-eter.	Thermom-eter.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM AUGUST 31, 1883, TO SEPTEMBER 7, 1883.

SHUFELDT, ROBERT W., captain and assistant surgeon. Granted leave of absence for three months on surgeon's certificate of disability, with permission to leave the Department of the South. Paragraph 3, S. O. 204, A. G. O., September 5, 1883.

WAKEMAN, W. J., first lieutenant and assistant surgeon. Assigned to temporary duty at Fort Sidney, Nebraska. Paragraph 2, S. O. 92, Department of the Platte, August 28, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING WEEK ENDING SEPTEMBER 8, 1883.

DIEHL, OLIVER, passed assistant surgeon. Detached from the Naval Academy and ordered to the U. S. S. Quinnebaug, European Station, per steamer of the 15th inst.

ANDERSON, FRANK, passed assistant surgeon. Detached from the U. S. S. Quinnebaug, on reporting of his relief, and granted leave of absence for three months.

AMERICAN GYNECOLOGICAL SOCIETY.—The eighth annual meeting of the American Gynecological Society will be held in Philadelphia, at the hall of the College of Physicians, on Tuesday, Wednesday, and Thursday, September 18th, 19th, and 20th. Papers are expected to be read as follows: Superinvolution of the Uterus, by Dr. Joseph Taber Johnson, of Washington. The Importance of Cleanliness in Surgical Operations, by Dr. R. Stansbury Sutton, of Pittsburg, Penn. Some Points connected with the Subject of Dysmenorrhœa, by Dr. C. D. Palmer, of Cincinnati. An Unusual Form of Abdominal Tumor, three cases, by Dr. Thaddeus A. Reamy, of Cincinnati. Is Extirpation of the Cancerous Uterus a Justifiable Operation? by Dr. A. Reeves Jackson, of Chicago. A Biographical Sketch of Dr. Nathan Smith, Founder of the Dartmouth Medical College

(being the President's Address), by Dr. Gilman Kimball, of Lowell, Mass. The Management of Accidental Puncture and other Injuries of the Gravid Uterus as a Complication of Laparotomy, by Dr. Charles Carroll Lee, of New York. A New Method of Operating for Fistula in Ano, by Dr. Edward W. Jenks, of Chicago. Ergot: the Use and Abuse of this Dangerous Remedy, by Dr. George J. Engelmann, of St. Louis. Congenital Fissure of the Female Urethra, with Exstrophy of the Bladder, and Menstruation after Extirpation of the Ovaries, by Dr. Henry F. Campbell, of Augusta, Ga. Remarks on Chronic Abscess of the Pelvis, by Dr. William H. Byford, of Chicago. A Discussion on Death after Labor will be opened by Dr. Campbell.

RHODE ISLAND MEDICAL SOCIETY.—A quarterly meeting will be held in Masonic Hall, Newport, on Thursday, September 20, 1883, at 11.30 A. M. The proposed law pertaining to the abolition of the coroner system in Rhode Island and the substitution thereof of a system of medical examiners will be a prominent subject for discussion. **G. D. HERSET, Secretary.**

BOOKS AND PAMPHLETS RECEIVED.—The Principles and Practice of Surgery. Being a Treatise on Surgical Diseases and Injuries. By D. Hayes Agnew, M. D., LL. D., Professor of Surgery in the Medical Department of the University of Pennsylvania. Profusely Illustrated. Vol. III. Philadelphia: J. B. Lippincott & Co. 1883.

Anatomy, Descriptive and Surgical. By Henry Gray, F. R. S., etc. With an Introduction on General Anatomy and Development. By T. Holmes, M. A. Cantab. The Drawings by H. V. Carter, M. D. Edited by T. Pickering Peck. A new American from the Tenth English Edition. To which is added Landmarks, Medical and Surgical, by Luther Holden, F. R. C. S., with Additions by William W. Keen, M. D. Philadelphia: Henry C. Lea's Son & Co. 1883.

Observations on the Management of Enteric Fever according to a Plan based upon the So-Called Specific Treatment. By James C. Wilson, M. D. Read before the College of Physicians of Philadelphia, January 3, 1883. (Reprint.)

The Topographical Relations of the Female Pelvic Organs. By Ambrose L. Ranney, A. M., M. D. With Twenty-Two Wood Cuts. New York: William Wood & Co. 1883.

Original Articles.

CONSUMPTION IN NEW ENGLAND.

BY E. P. HURD, M. D., NEWBURYPORT, MASS.

IV.

THE PHARMACEUTICAL TREATMENT.

THE medicinal treatment of phthisis is generally unsatisfactory, except so far as it is auxiliary to the hygienic. Common experience demonstrates this. Hygiene is of more value than drugs, and of the latter there are but a few on which we can rely. Reference to very many articles in back numbers of the Boston Medical and Surgical Journal, devoted to the treatment of this formidable disease, — and scarcely any disease has such a literature as phthisis, — only results in the conviction that while cod-liver oil, compounds of phosphorus, tonics and stimulants, with medicated inhalations, may be of material benefit associated with the hygienic measures insisted upon in a previous article of this series, alone they are of but little advantage as curative means, and that when the phthical invalid is obliged to remain at home and in-doors, doing little or nothing to avert the dire malady but take medicine, and await the daily visits of his physician, — hard as it is to confess it, it is true, — the patient is already past cure.

The following notes of two cases from my record book are a sufficient illustration of the disease in its gravest aspect. Observations such as these are of almost daily experience : —

PHTHISIS IN THE STAGE OF EXCAVATION; CAVERNOUS RESPIRATION AND PECTORILOQUY; AMPHORIC PERCUSSION RESONANCE; SLOW PROGRESSIVE EMACIATION; ALL TREATMENT INEFFICACIOUS.

Mary E., aged nineteen; Irish; domestic; father and mother healthy; no hereditary tuberculous antecedents. Two brothers and one sister have died of pneumonic phthisis. Patient was well and able to earn her living as domestic till about one year ago (May, 1882), when she "caught cold" and had a hæmorrhage. Since then there has been gradual emaciation and increasing debility, with evening attacks of fever and night sweats, harassing cough, and muco-purulent expectoration. The physical signs all point to extensive excavation at the apices of both lungs; in the left infra-clavicular region the percussion resonance is amphoric, and auscultation gives gurgling râles; on the right side near the axilla there is also hollow breathing and bubbling, with cracked-pot percussion sound.

The above description applies very nearly to the case of Mrs. B., of Madison Street, with the exception that the excavation signs are limited to the left side. Mrs. B. has been a consumptive for two years, and her disease has been apyretic; she is American by birth, and has suffered from overwork, abuse (her husband is a brutal sot), and deprivation of food, clothing, and fuel. There is, besides, an inherited tendency to tuberculosis, and (what Dr. H. I. Bowditch considers a most important factor in the ætiology of consumption) for several years after her marriage Mrs. B. lived in a marshy locality in a tenement shaded by trees; there was, moreover, always water in the cellar.²

¹ Continued from p. 484, vol. cviii.

² I can here only just allude to the valuable series of papers by Dr. H. I. Bowditch, in the Atlantic Monthly for 1869, on Consumption in America. The influence of sub-soil moisture in the genesis of this disease is there clearly shown. Not by any means the least

The question of treatment as applied to the case of these two patients is reduced to great simplicity. The impotence of therapeutics finds here a striking illustration. No remedy can save them; nothing can much prolong their existence. It is the reproach of our profession that the most cheering word in our power to pronounce to such patients is the promise of euthanasia.

Nutrients, hypophosphites, alcoholic stimulants, cod-liver oil, tonics are all ruled out; it is impossible to suggest anything under any of these heads that can be taken in quantities sufficient to arrest the disease or even produce any amelioration whatever. Both have pneumogastric irritability. They must be allowed to eat or drink just what they most crave, and nothing relieves the cough and systemic irritation but morphia. They are taking Magendie's solution, ten drops *pro re nata*.

The night sweats are for the most part persistent, despite the use of atropia, small doses of jaborandi, and other anhidrotic medicaments.

The sputum of both of these patients has been examined for tubercle bacilli, and the presence of these microphytes has been determined by the proper staining fluids, a one fifth objective being used.³

The medicinal treatment of phthisis comprehends (I.) the germicide treatment; (II.) the constitutional treatment; (III.) the symptom treatment.

(I.) Since the belief in the bacillus theory of phthisis has become prevalent, there has been a strong and predominant interest in the local antiseptic or germicide treatment of the disease. Internal medication directed against the supposed germ cause is, of course, not to be thought of. Nobody is foolish enough to suppose that the destructive parasitic agent of tuberculosis can be reached through the blood, especially since, as Pollock remarks,⁴ the same cause which has cut off a portion of the lung by strangling its vessels has also rendered it impervious to remedies approaching it through the circulation. To treat the lungs antiseptically, then, is to treat them by medicated inhalations. The various steam atomizers and spray apparatuses here find a place with pulverizations⁵ of creosote, carbolic acid, eucalyptus, etc. It being inconvenient to use a spray other means have been proposed for impregnating the air of respiration with antiseptic substances. The old-fashioned inhaling bottle has gone out of use,⁶ but the patient is sometimes made to in-

of Dr. Bowditch's valuable contributions to American medicine is his demonstration of the influence of damp, shady localities in favoring and fostering the tuberculous diathesis.

³ Since writing the above brief report both of these patients have died.

⁴ Lectures on Phthisis, London Lancet, 1883.

⁵ With regard to the remedial value of pulverizations in phthisis, in 1862 there was a long discussion before the Academy of Medicine, Paris, as to whether atomized liquids could penetrate the lungs or even the smaller bronchi. Gratiolet, Sales-Giron, and others claimed that this penetration was possible, others, as Fournié, Delore, maintained that pulverized liquids could not penetrate even the trachea. In cases where Delore caused atomizations of iodine and iodide of potassium to be respired he never found a trace of these medicaments in the urine of the patients who were the subjects of the experimentation. Fournié denies the penetration of pulverized liquids, but admits that of solids inhaled in the form of dust. Walderburg, while owning that a minute quantity of the atomized vapor reaches the air-passages, shows that the far greater part is lost in the pharynx and larynx, and that at the most, after a few minutes' inhalation, a few drops may penetrate the trachea and bronchi. Beaumetz, while summing up results, concludes that these atomizations do no good in phthisis or chronic bronchitis, while excellent in diseases of the pharynx. Dujardin-Beaumetz, *Leçons de Clinique Therapeutique*, t. ii., p. 526.

⁶ It is nevertheless true that in cases of phthisis with constant teasing cough and profuse muco-purulent expectoration the "old fashioned inhaler" is often of wonderful remedial efficacy, allayin

hale, and with advantage, the oil of pine made into a mucilage, and added in small quantities to hot water in an ordinary coffee pot. The formula and the process originated, I believe, with the author of the article on Consumption in Reynolds' System of Medicine. The naso-oral respirator is said to fulfill conditions which intermittent spraying or the inhalation of medicated steam can never do. Mackenzie medicates his respirator with a mixture of one part carbolic acid to three of creosote, and claims excellent results from the continuous wearing of the apparatus.¹ Respirators of charcoal, wool, cork, wire, and vulcanite have been described. Many of these are patented in England. The great objection, however, to respirators is their inconvenience and the difficulty which is experienced in getting patients to wear them continuously. Of all the antiseptics ever suggested for consumptives that of Cullimore in the *Medical Press and Circular* seems especially to commend itself. It is sulphurous acid vapor mingled with oil of pine, kaolin, oil of eucalyptus, or benzoic acid. These germicide substances are dropped on a bit of sponge in a wide-mouthed bottle, or inhaled from a pitcher of hot water. Full directions for the preparation and use of these bacillicide compounds are given in the number of *Braithwaite* for January, 1883.²

What benefit are we likely to derive from these medicated inhalations in phthisis? Is there positive clinical evidence in their favor?

Empirically they have long been used, in the belief that they favorably modify local inflammatory processes, disinfect the pulmonary secretions, allay irritation, and promote the cicatrization of cavities. Thirty or more years ago Drs. Minot, Pineo, Kneeland, and others reported in this journal successful results from the use of fumigations and inhalations in phthisis. It is probable that the inhalation treatment was more popular then than now. Kneeland especially insists on the importance of what he calls "the surgical treatment" of phthisis.³

It would be presumptuous skepticism to gainsay all the testimony in support of this direct medication. Some benefit is doubtless often derived; the cough is allayed, local congestions arrested, putrefaction of the bronchial secretions prevented, and respiration facilitated. There is, however, no evidence that inhalations, sprays, atomizations, or fumigations have any efficacy in destroying the micro-organisms⁴ whose mul-

irritation, and facilitating expectoration. No more useful formula was ever devised than the following, which was given to the profession in the *Boston Medical and Surgical Journal*, in 1857, by Dr. Edward Jenner Cox:—

R Ext. conii	3ij.
Ext. opii	3i.
Paregoric	3iss.
Bals. copaiba	3ss.
Spts. picis liquid	3ii.
Cherry-laurel water	3i. M.

Sig. Add a teaspoonful of the above to five tablespoonfuls of hot water in the inhaler, and inhale four or five times a day.

¹ Braith. Ret., part 86, page 95.

² No. 1 is as follows: R Ol. pini Sylvestris, ℥ lxxx., kaolin, gr. xx., acid sulphurosi, ad 3i. M. ft. inhalatio. Five to ten drops to be inhaled three times a day.

No. 2. R Ol. eucalyptus, ℥ lxxx., kaolin, ʒi., acid sulphurosi, 3i. M. ft. inhalatio.

No. 3. R Acid sulphurosi, 3ss., tinct. benz. co., 3ss. M. ft. inhalatio.

The essential ingredient in these inhalations is the vapor of sulphurous acid, the oils being used to disguise the odor, and render the acid vapor less irritating. The benzoin combination is the most generally useful.

³ Boston Medical and Surgical Journal, February 18, 1858.

⁴ Schueller, of Greifswald, and Rokitsansky, of Insbruck, claim

tiplication and whose ravages are supposed to be such important *secondary* factors in the disease. I say *secondary*, for I look upon the constitutional diathesis as of *primary* importance, as stated in No. 2 of this series. If the soil be not first fit for the bacillus it will not find a habitat there. If it be *fit*, there is no direct medication known to science which will prevent the development, growth, and multiplication of the parasite. It cannot, then, be too strongly urged that the hygienic and tonic medication constitutes the best germicide medication, and that pure, dry, bracing out-door air is the very best antiseptic.

(II.) The constitutional treatment of phthisis comprises all those remedial agents which assist nutrition and promote systemic vigor. Chief among these are cod-liver oil, the phosphates and hypophosphites, bitter tonics, alcohol, and arsenic. With regard to cod-liver oil, I have already referred to this incomparable nutritive medicament in the paper on hygienic treatment. With arsenic in phthisis I confess I have no favorable experience to report. Both arsenic and cod-liver oil undoubtedly increase the globular richness of the blood, as Cutler and Bradford have shown by their experimental researches.⁶ Beaumetz and Jaccoud place arsenic at the head of reconstituents, giving it in the form of granules of Dioscorides, Fowler's solution, or Bourboule water. The latter can be obtained in Boston, and is an excellent arsenical mineral water for phthisical patients.

As for cod-liver oil, we residents of the coast prefer the home-made preparation from the fresh livers of the codfish. I have never seen any foreign oil so sweet and so well borne as that which is made at our own port. Where the appetite is good, a tablespoonful of this oil is taken after each meal, and generally with no impairment of the digestion. If a tablespoonful cannot be borne, a less quantity may be taken. I have known a little porter or whiskey taken after the oil to cause it to be better assimilated. How much may daily be ingested to advantage? All that the stomach will tolerate, provided the appetite for other food be not destroyed in consequence. I have seen the best results from the oil when large quantities were taken, say four or five ounces a day. In whatever stage of the disease, where cod-liver oil is well supported, amelioration always attends its use. Unfortunately, however, in this stage of softening, and in febrile conditions, it is, as a rule, not borne.

Of the various emulsions in the market, I have had the best success with that of Phillips, which certainly contains the oil globules in a very minute state of division. I have seen this emulsion taken with benefit—and for a long time—by patients with delicate stomachs which revolted against the pure oil.

As regards the hypophosphites and phosphates in phthisis, much has been written, and there is much conflicting testimony. There is probably nothing specific about them. Alone they have never cured and never can cure consumption. They doubtless have an important subordinate place in the therapeutics of this

successful results in arresting the evolution of tuberculosis by inhalations of benzoate of soda. The latter used a five per cent. solution, causing fifty grammes of the salt daily to be inhaled, and reports fifteen cases. Klebs uses the benzoate both locally by inhalation and internally, giving frequent gramme doses. Guttman claims some relief from cough by this means, but thinks that the inhalation of plain water does as much good. Senator, Fritsche, Wolff, and others have given the benzoate treatment a fair trial, and pronounce it inefficacious, except possibly as a local palliative.

⁶ American Journal Medical Science, January, 1878.

disease, aiding nutrition, and possibly being appropriated, to some small extent, in supplying the waste of the organic phosphorus compounds.¹ Certain it is that they are given, and given largely, by almost every physician in the land, whether any definite results are seen from them or not. It is almost a matter of routine to prescribe somebody's syrup of the hypophosphites to every phthisical patient, and if the action of the mineral ingredient seems to be nil, the small quantity of strychnia in these syrups tends to keep up the appetite.

A favorite combination in the treatment of early phthisis, one that is sometimes well borne, and gives good results even in advanced stages, is the following:—

R Syrup lactophosphate lime, }
Cod-liver oil, } āā 3iv.
M. Dose. A dessertspoonful, to be taken frequently through the day.

One patient of mine, Mrs. L., of Merrill Street, took this preparation till almost the last period of her sickness, even when there were large excavations in the lungs and the appetite was entirely gone; it seemed to be nutritive and supporting, and the patient fancied that her cough was better under its use.

As for the iron preparations in phthisis, I think that common experience is against their use altogether, despite the anæmia which attends the disease. As a matter of fact they are not well borne, irritate the intestines, and aggravate any local lesion, in the lungs or elsewhere.

Glycerine is often prescribed as a tonic and nutrient, and taken in moderate doses it seems often to do good. Given with whiskey it is well supported, and relieves the cough. Alcoholic stimulants have an important place in the treatment of phthisis, especially the bitter ales, which I have repeatedly prescribed, and with marked advantage.

III. SYMPTOM TREATMENT. (a.) *The Cough.* The cough is an expression of the irritation of the respiratory passages. There are foreign bodies (tubercles) in the pulmonary parenchyma, there is a morbid secretion in the bronchi, the pulmonary and bronchial mucous membrane is in a state of erethism from hyperæmia. These three factors of cough need to be taken into account in instituting the treatment. The first and last factors are constant, the second is not so constant. The irritation (from whatever source) is referred to the pharyngeal plexus of nerves,—pharyngeal branches of the pneumogastric and spinal accessory, glosso-pharyngeal, and sympathetic. The intimate association, by communicating fibres and anastomoses, of this plexus with the nerves which innervate all parts of the respiratory apparatus, motor and sen-

sory, and the common origin of the principal of these nerves in the medulla oblongata, is a striking fact in connection with the phenomenon of cough.² The sensation of titillation which provokes cough is comparable to the sensation of thirst, both of which are the local expression of an imperative organic demand.

The cough of phthisis is the symptom the most persistent, the most annoying, the one for which the patient most imperatively demands relief. "O, if you could cure this cough I should be well!" is a frequent exclamation. The reply is sometimes forced upon us, "If you could be rid of the tubercles in your lungs, you would be rid of your cough." Here, then, is the important fact, that in order to cure the cough we must remove the cause of the cough, the tuberculous irritation, which is also provocative of the hyperæmia and the morbid secretion. For this we must depend on the hygienic régime and on tonic medication. The following case from my note-book is to the point:—

Patient, Eliza C., aged twenty-one; Irish; a servant girl in my family, 1867. Parents healthy people; one sister died of consumption in 1864. In February Eliza, previously in good health, took cold, and a severe cough set in, with fever and night sweats. The physical signs of a tuberculous deposit in the tops of both lungs were manifest. She persisted in performing her duties as house-maid. The cough was almost incessant, and for the most of the time dry; now and then it was attended by hæmorrhage. There was a marked vespertine febrile movement. This cough was a sore annoyance to the poor girl; she was unwilling to take cod-liver oil (which, in fact, was not supported), tonics did not suit, but she took quantities of squills, wild cherry bark, senega, in decoctions, medicated with paregoric, syrup of poppies, syrup of morphia, etc., which gave slight palliation. An occasional full dose of antimonial wine seemed to do the most good, particularly if followed by nausea; it promoted secretion, and thus diminished hyperæmia. I insisted on Eliza going to her home in the country, to rest from all work, to be much in the open air. She did so, and during the summer months recovered in great measure her flesh, strength, and appetite, the cough and night sweats for a time disappeared, only, however, to return with a re-awakening of the disease (which speedily became fatal) in the autumn.

The only means by which we can directly modify or alleviate the cough is by remedies which diminish hyperæmia and irritability. We may lessen the catarrhal inflammation by our counter-irritants and expectorants. As for counter-irritation, I have rarely seen much benefit in phthisis from the ordinary means,—painting with tincture of iodine, frictions with croton oil liniment till the appearance of the eruption, cantharidal vesication, etc.³ Theoretically, revulsion might be expected to do good, practically we are continually disappointed in it.

As for expectorants, the term is an arbitrary one, and may include a great variety of remedies. Whatever influence expectorants have on the respiratory apparatus is limited to the bronchial mucous membrane; here even they have a very restricted action, and, as Stillé observes, this action is addressed almost exclusively to that condition in which the bronchial secre-

¹ The phosphate of lime, as a nutrient and cell-producing agent of great power, was first brought to the notice of the profession by articles in the London Lancet for 1851. Dr. Stone, of New Orleans, made trials of this salt, and recommended it to American practitioners. It is well known that the salts of phosphoric acid are essential to the formation of azotic compounds, and in regard to the phosphate of lime it was shown that it increases the production of cells; the tribasic phosphates play an important part in the growth and development of plants, and are found in all seeds; in all chronic diseases of the human subject attended with emaciation, phosphates are excreted in excess. From theoretical considerations, then, these salts would seem to be indicated in phthisis.

The following combination, of which a wine-glass full may be taken after meals, is a favorite one in the Hôpital St. Antoine (Lectures on Phthisis, by D. Beaumetz): R Phosphate of soda, six grammes; phosphate of potash, three grammes; wine, two hundred grammes; syrup aurantii corticis, sixty grammes. M. Vide Ira Warren in Boston Medical and Surgical Journal, 1852, first vol., p. 201.

² Gueneau de Mussy, Clinique Medicale, t. i., p. 615, has dwelt largely on this anatomical and physiological consensus.

³ This is also the experience of Dr. J. Hughes Bennet. Vide article on Phthisis in Reynolds' System of Medicine.

tion is excessive and morbid.¹ Simple congestion is sometimes relieved by a diffusible stimulant, such as whiskey, which acts by exciting the whole vascular system, including that which is especially affected.² A favorite cough medicine is composed of whiskey and glycerine, which is prescribed in all stages and conditions of the disease. An ounce of glycerine is mixed with five or six ounces of whiskey, and taken freely during the day, in small quantities. The glycerine has special virtues of its own, being nutrient and tonic; it is a favorite remedy with Jaccoud, who regards it as scarcely inferior to cod-liver oil. It has also demulcent properties, soothing the dry and irritable throat. The "rye and rock" which is sold by our grocers and apothecaries is often made of inferior whiskey, and is not comparable to the compound with glycerine.

In cases where the bronchial secretion is excessive, remedies are indicated which help restore tone to the lax vessels, and which are directly stimulant to the morbid mucous membrane. Here medicinal inhalations are indicated (tar, balsams, turpentine, creosote, etc.), and certain remedies which are eliminated by the air passages, and have an alterative effect. Creosote, in doses of from half a drop to two drops with alcohol and some pectoral syrup, is a favorite medicament with foreign practitioners. I confess that I have never seen any marked benefit from its use. The simple or compound tincture of benzoin has been of much greater utility. Tar (as tar water, or syrup of tar), ammoniacum, copaiba, squills, and senega are much in use in these chronic stages with profuse secretion, and are all, probably, more or less useful. Where the secretion is thick and scanty, ipecacuanha and alkalies, especially chloride of ammonium, have certainly considerable efficacy. Where the cough is perfectly dry it is of no use to give expectorants; demulcents and sedatives are here indicated. And always throughout the disease we are obliged to resort to these latter medicaments. Demulcents probably aid principally if not entirely by their topical effect, while sedatives (the entire group of narcotics) and anæsthetics allay hyperæsthesia of the terminal sensory nerve filaments in the lungs, bronchi, and pharynx, and thus palliate the cough. The type of these medicines of course is opium, and sooner or later some form of this medicament becomes our chief reliance. Syrups of morphia or codeia (codeia, according to Bartholow, is far preferable, and is, *par excellence*, the sedative of the pneumogastric) are the most eligible forms in which to give the opiate. Momentary inhalations of chloroform and alcohol (one part to three) will sometimes relieve a stubborn cough, and a few drops of chloroform in water taken during a paroxysm gives palliation. When I was hospital interne in 1864 I used often to see Collis Brown's chlorodyne prescribed as an adjuvant to cough medicines, and I am now in the habit of ordering fifteen drops of Parke Davis & Co.'s *chloranodyne* where there is indication to soothe a harassing cough and procure sleep. (The formula of chloranodyne is well known to the profession.)

I do not think that there is in wild cherry bark enough hydrocyanic acid to afford any perceptible sedation to the irritable broncho-pulmonary mucous membrane (at least in any ordinary dose).

(b) *The Night Sweats.* The pathogeny of the night sweats of phthisis is ill understood. Profuse nocturnal

sweating is always an index of debility, but it does not accompany all states of debility; it bears, however, a marked relation to exhausted conditions of the respiratory system. When the respiratory centre is exhausted the excretory function of the sudoriparous glands is exalted, the skin being to a certain extent vicarious with the lungs. In disease of the lungs with limitation of the field of hæmatosis, there is increased elimination by the skin, and when, as in deep sleep, the pulmonary excretion is at its minimum, hidrosis is at its maximum, the vaso-secretory nerves being stimulated to action by an excess of carbonic acid in the blood.³

The night sweats of phthisis are, however, neither physiological nor salutary. If it were proper to credit nature with any good intention, the fact is patent that elimination is soon overdone, the blood is rapidly impoverished of its water and salts, chlorides, phosphates, and sulphates. It is, moreover, susceptible of daily proof that arrest of these sweats is attended with benefit to the patient; appetite and strength at once improve. So marked is this gain that Fothergill considers that the most important indication in the treatment of early phthisis is to stop the night sweats.

Of all the medicinal means for checking hidrosis in phthisis probably the most effectual is belladonna or its alkaloid, atropia. Atropia is more reliable than belladonna, although one half grain of the extract of the latter, or ten drops of the tincture, at bed-time, is often efficacious. Atropia is a special stimulant to the respiratory centre, and proves beneficial in exhausted states of that centre, and besides making the necessity for hidrosis less it locks up the sudoriparous glands, being an arrester of secretion.

A convenient way to administer atropine for night sweats is to rub up a grain with one hundred grains of white sugar, and divide into one hundred powders. Of these one may be given at five o'clock P. M., and another about bed-time. This will generally arrest the sweats. One or two drops may be given at bed-time of the British solution, enough being administered to obtain the physiological effects of the drug, among the most noticeable of which is dryness of the throat. J. Milner Fothergill has an excellent pill which alleviates both cough and night sweats. It consists of one fourth grain morphia, one fortieth grain atropia, one grain of capsicum, and three grains of pil. aloes and myrrh.

Other means for arresting the sweats are in vogue, such as sponging the patient all over with cold vinegar (to which some add capsicum); the use of a powder, which is dusted over the whole body at bed-time, consisting of salicylic acid, one part to six or eight of lycopodium and starch;⁴ sponging with hot water at night; causing the patient to be aroused before the time of sweating, giving him a light lunch, and bathing hands and face; two to five grains of quinine at bed-time; a pill of oxide of zinc three times a day, etc. Dr. Murrell has recently introduced picROTOXINE to the profession as a valuable anhidrotic, one gramme to 240 grammes water; dose, one to four minims three times a day, last dose at bed-time. He claims remarkable success with this remedy. It does not make the skin too dry, while atropine often seems to parch it up. M. Charteris proposes hypophosphite of lime, of which

¹ Therapeutics and Materia Medica, vol. ii., p. 493.

² Ibid.

³ This is substantially Fothergill's explanation. Vide Braithwaite's Ret., part 78, page 74.

⁴ New York Medical Record, vol. xvii., p. 287.

he recommends three grains three times a day. He claims excellent results. Lastly, we have seen small doses of *jaborandi* recommended on the principle of *similia similibus*.

In my own experience the atropine treatment with night feeding and sponging has been the most successful.

(c.) *The Hæmoptysis.* The hæmoptysis in phthisis results either from congestion around a tuberculous deposit or from the rupture of a blood-vessel or (according to Damaschino) small aneurisms in a cavity. The most valuable means for combating this always alarming accident are subcutaneous injections of ergotine, two grammes to thirty grammes of water. Squibb's fluid extract of ergot may be given in doses of ten drops every hour, or even every half hour. Dobell's solution, which consists of an ounce of compound infusion of roses, to which is added twenty drops fluid extract of ergot, twenty of tincture of digitalis, ten grains gallic acid, fifty of sulphate of magnesia, and ten drops dilute sulphuric acid, — the whole to be taken at one dose, and repeated every three hours till the hæmorrhage ceases, — is a deservedly popular prescription, combining the ordinary hæmostatic remedies with a cardiac sedative, digitalis.

(d.) The diarrhœa of phthisis is often very stubborn, depending as it does generally on intestinal tuberculosis and ulceration. It requires a rigid dietary regimen of milk, flour gruel, aided, it may be, by pancreatic emulsion, raw meat, etc., with opium in sufficient doses. The best results, in my opinion, attend the combination of opium with bismuth, one grain of the former to ten, or even twenty, of the latter.

(e.) The fever of phthisis, which is generally of a suppurative, remittent, or intermittent type, is little amenable to aconite, veratrum, and other popular febrifuge medicaments. If I may again refer to personal experience, I would say that I have had no success in treating this fever with the large doses of quinine and salicylic acid which have been advised, while I have certainly been more successful with cold sponging and the administration of mineral acids. The euechlorine mixture, recommended by Watson, has at times been of marked service.

A CASE OF SUPPURATIVE HEPATITIS DUE TO A PIN IN THE VERMIFORM APPENDIX.

BY M. D. CHURCH, M. D.

ON Saturday, A. M., November 11, 1882, I was called to see E. K., an unusually bright, active child of nine years, who on the day previous returned from school complaining of lassitude and great weakness, which came over her during the afternoon while in school. In reply to her mother's inquiry she said she felt no pain in any part; some household remedies were administered during the evening and the child was placed in bed, where she passed a restless night. Upon inquiry I learned that the child had always been healthy, although she looked delicate; family history good. No history of an accident or injury could be obtained. Her mother said her appetite was always precarious, and she thought declining during the last few days. Bowels usually inclined to constipation. Examination showed a girl rather tall for one of her years, with delicate skin and features; cutaneous blood-vessels remarkably prominent over the entire body, es-

pecially the trunk. Percussion and auscultation of the chest and abdomen revealed nothing abnormal; deep pressure in either hypochondrium showed no tenderness, tumor, or swelling. Examination of the urine on the following day showed the kidneys to be in a healthy condition. At the time of visit the pulse was 90, respiration normal, temperature 99° F. From the 11th to the 17th inst., the child insisted upon being dressed and lying upon the lounge during the day, and her general condition remained about the same as at my first visit until the 18th, when she had (as her mother described to me) a "nervous spell," during which she was very restless and thirsty; cheeks became red, although the skin was very harsh and dry, and after an hour slightly moist from perspiration, when she appeared as on days previous. This was repeated on the day following at nearly the same hour. On the 20th she was suddenly seized with a "shivering spell," and complained of feeling cold, accompanied with some nausea and occasional vomiting. The chilly sensation soon passed off, and pallor was replaced by flushing and suffusion of the face. These phenomena having occurred in the P. M. after my visit in the morning, I changed my hour of visitation, and on the following day (November 21st, 4.30 P. M.) found the patient in profound chill, shivering, nauseated, and vomiting, vomitus consisting of ingested fluids and bile. The chill lasted about forty-five minutes, and was quickly followed by flushed face, quickened pulse, thirst, and rise in temperature. Temperature at height of fever 103° F.; pulse 112; respiration 28. Ordered quinine in cachet form, two and a half grains each, to be given till roaring in the ears was complained of. The patient said she had no pain whatever. On the following day I found her comfortable, and she said she felt much better; ordered the quinine continued in sufficient quantity to produce slight cinchonism for at least four hours previous to time of expected chill. But the patient strongly objecting, the drug was not given as directed, and that night at nine P. M. a chill occurred, accompanied by retching and vomiting. Insisting upon the regular exhibition of the drug, there were no chills or chilly sensations during the succeeding four days, although the pulse remained accelerated 100.

On the 27th she complained of headache, and the quinine was discontinued. Patient seemed quite bright and cheerful, and at time of visit said she felt much better. Percussion and auscultation of the chest gave negative results; no pain or tenderness in any part was complained of, although deep digital pressure was made in both hypochondria, and percussion and pressure over the liver and spleen. Percussion over the liver seemed to indicate a slight increase in the area of hepatic dullness upwards and towards the median line of the body, also slight enlargement of the spleen.

On the 28th patient had another chill, followed by fever, with nausea and vomiting. There being such a repugnance to the quinine when administered by the mouth, it was combined with nutrient enemata, which became imperative in consequence of the weakness and irritability of the stomach.

On the 29th, after a restless night, patient had a chill at five o'clock A. M., when nausea, retching, and vomiting became severe; yet she said she had no pain. Being called at nine A. M., I ordered for the vomiting sodii bicarb. 10.00, oil absinthii .20, aquæ 100.00, teaspoonful every hour. At four P. M. found the patient quite comfortable; had retained nutrient enemata, also

a small quantity of brandy and beef-juice. The fever following the chill in the A. M. reached the highest point observed during her illness, 105.8° F. Directions were given to continue the quinine if the stomach would permit, which was begun at the time of my visit in the P. M.

November 30th, five P. M. Pulse 100; respiration and temperature normal. Found the patient sweating gently; said she felt no pain or tenderness while being examined; had taken one grain of quinine during the day.

On the following morning, December 1st, I learned that a chill came on at ten P. M. the day previous, between which and the appearance of fever there was an interval of over half an hour, during which the patient slept quite soundly, when a rise of temperature commenced which did not exceed 102° F., and was short in duration.

On the 2d of December she complained of severe pain in the right hip and thigh of a lancinating character, for which warm applications were prescribed, and which soon disappeared. Examination of the liver and spleen showed no thickened margin or perceptible tumor or fluctuation, but area of dullness over both organs seemed increased, so that a line of dullness extended almost across the body. Dr. S. E. Wyman being called in consultation, remarked that there was a continuous area of dullness across the body, whether due to enlargement of the liver entirely, or both spleen and liver, he would not say positively. During the examination deep digital pressure was made in both hypochondriac regions, and pressure and percussion over the liver, but no tumor or tenderness was found, neither was pain excited; no râles or dullness were found about the lungs.

On the following day, December 2d, while vomiting during a chill, the patient complained of epigastric pain, which was felt only while vomiting.

December 3d. Considerable cough, while the chilly sensation was complained of, and the patient wanted to lie upon the left side; complete anorexia; marked emaciation; mind perfectly clear. Pulse 98; respiration and temperature normal. Nutrient enemata rejected; great weakness complained of, but no pain.

December 4th. Examination of urine showed diminished specific gravity (1013), greatly diminished chlorides, increased coloring matter, mere trace of albumen, but no casts. During the night previous there had been two involuntary diarrhoeal discharges.

December 6th. A chill came on at six A. M., when nausea and vomiting became persistent; much pain was complained of while vomiting, and referred to the stomach. The chill was followed by rise of temperature which terminated in profuse perspiration.

Dr. J. T. G. Nichols saw the patient in consultation on this day, and after a careful examination said that he would not assert positively that there was splenic enlargement, although the patient complained of tenderness whenever pressure or percussion was made over this organ. The diagnosis that seemed most probable was pyæmia from some internal cause, probably a pylo-phlebitis. The extreme irritability of the stomach precluded the use of any medicines except such as could be administered in form of enemata. Soda-water and champagne in teaspoonful doses were administered at intervals of half an hour, and for twenty-four hours, immediately returned.

December 7th. Patient had a chill at one P. M.,

short in duration, and quickly followed by fever. Pulse at time of visit, five P. M., 112; respiration 32; temperature 104.5° F. Examination of urine showed diminished quantity, specific gravity, chlorides and phosphates; large trace of albumen and bile coloring matter.

On the 9th the amount of urine excreted greatly diminished (480 grammes) in twenty-four hours, was high colored, and contained considerable bile. The patient seemed much weaker, and had a peculiar pinched and emaciated look. The conjunctival mucous membrane and scleral coat slightly stained with bile pigment.

December 10th. Pulse 104; respiration 28; temperature 100° F. The patient complained of itching over the entire body; skin was dry and markedly icteric; tenderness manifest over the region of the liver and spleen on palpation or percussion, but no pain.

December 12th. Pulse 100; respiration 24; temperature normal; skin deep yellow in color; tongue thickly covered with a dirty brown incrustation; area of hepatic dullness much extended; pressure or percussion over the region of the gall-bladder causes pain; no dyspnoea. Chest examination showed the heart and lungs to be in a healthy condition. Examination of the urine at this stage showed the amount of albumen to be one fourth per cent., also to contain hyaline, granular, and epithelial casts, and much degenerated renal epithelial cells, all of which were deeply bile-stained. The amount of urine passed in twenty-four hours 180 grammes. One normal dejection during the day.

December 13th, thirty-third day of illness. Pulse 120; respiration 32; temperature normal. The patient passed a restless night; nutrient enemata retained. The amount of urine passed in twelve hours 120 grammes; the urine thick, and contains large amount of bile; bits of cloth or paper dipped in it were deeply stained with bile pigment. During the day there were two dejections deeply stained with bile coloring matter. Tenderness over the gall-bladder more marked, but no tumor or fluctuation discernible; no pain except when pressure is made over the liver.

December 14th, 9.30 A. M. Pulse 112; respiration 32; temperature normal. Patient vomited once during the night; vesical tenesmus marked; amount of urine passed in twelve hours ninety grammes; mind clear; no pain except on pressure; auscultation shows diminished vesicular murmur at the apex of the right lung, also over upper lobe of the left lung in front, with fine mucus râles; the patient complained of cold feet and limbs; assumed the supine position, with limbs sharply flexed on the body; the teeth covered with sordes; the bright yellow color of the skin had given place to a greenish tinge. Five P. M. No nausea or vomiting during the day; the amount of urine passed since the morning visit 150 grammes, lighter in color, and the amount of bile, as indicated by the color test, diminished; the countenance was more composed; mind clear; no cough or pain; pulse 120; respiration 32; temperature normal.

December 15th, ten A. M. Pulse 116; respiration 32; temperature 99° F. Patient quite restless till midnight; slight nausea and vomiting in the early morning preceded by a feeling of coldness; amount of urine during last twelve hours 150 grammes; the amount of albumen increased nearly one half per cent.; nutrient enemata during the night and morning returned; the greenish tinge of the countenance had

nearly disappeared; color of the skin a bright yellow; area of dullness and tenderness over the liver increased, but no tumor or fluctuation could be made out; no pain experienced except when pressure was made or the patient turned upon the right side; patient's mind clear, and she said she knew she could not recover. Half past eight P. M., same day, was called, and found the patient breathing rapidly, and much excited and talkative; pulse 116; respiration 60; temperature 99° F.; pulse very feeble, and respiration labored. When asked if she was suffering pain, she said no; neither could I discern any obstruction to

respiration. The patient asked for some cake and milk, of which she partook, and said she felt better, and was ready and willing to die.

December 16th, 9.30. Pulse 112; respiration 36; temperature 97° F.; patient talked nearly all night; mind perfectly clear; voice quite strong at the time of my visit; she said she had no pain except when pressure was made over the liver; abdomen quite tympanitic. The patient continued in earnest conversation with her friends until one o'clock, when she became comatose, and expired at 1.30 P. M., after thirty-six days of illness.

Autopsy performed and reported by Dr. S. E. Wyman, December 17th, twenty-two hours after death.

Body markedly icteric. Emaciation marked. Rigor mortis moderate. No external wounds. Panniculus adiposus reduced to minimum. On opening the abdomen an enlarged liver was seen extending nearly to the umbilicus. No adhesions of the peritonæum, but a slight amount of clear, colorless serum in the pelvis.

Heart normal in size, with, perhaps, a little less firmness of the muscular tissue. Valves intact. Recent clot in both ventricles, larger in the right.

Lungs were not adherent; both crepitate; everywhere discolored by bile pigment, and made to resemble wash-leather in color. At the extreme edge of the lower lobe of the right lung, on its anterior surface, were two small spots of consolidation, dark red in color, hard to the feel, and which on section showed no evidence of containing air or pus. In the upper part of the upper lobe of the left lung was a larger spot of hardened tissue, from which, on section, pus flowed. The lung tissue surrounding this spot contained more blood than usual.

Spleen normal in size and consistency.

Kidneys not enlarged. On section the cortical portion projected over the edge of the cut. The cut surface had a peculiar wash-leather color, and was deeply bile-stained. The cortical portion slightly swollen, suggesting parenchymatous inflammation. Capsule stripped readily, leaving a perfectly smooth surface.

The stomach contained about six ounces of greenish fluid, with a perfectly healthy condition of the lining membrane.

As soon as the abdominal cavity was opened the liver was seen to occupy more than the usual space in the lateral and downward directions. On the top of the anterior surface of the right lobe there was an area, measuring three inches in diameter, over which the general color was much darker than the surrounding liver tissue, containing irregularly-shaped, yellow-looking spots. This area was elevated above the surrounding parts, gradually rising from the edges towards the centre, and markedly fluctuating on pressure. There was no inflammation of the peritonæum over the liver. On turning up the organ *in situ* there was seen a second swelling on its under surface, in the lobus quadratus, just inside of (towards the median line of the body) the gall-bladder. This swelling was much more circumscribed (one inch diameter), with greater elevation. It was resting upon the duodenum (whose surface was stained a deep brown at the point of contact), and from it pus flowed upon the gentlest manipulation. After the removal of the intestines the liver was taken out. Weight two pounds, one ounce; measured eight inches in its transverse, and six and one half inches in its longitudinal diameter.

The gall-bladder was normal in appearance, and contained some bile. Duct pervious.

On section the liver was deeply stained with bile; acini quite distinct; general cut surface granular. On cutting through the larger abscess it was found that there was no distinct membrane inclosing it, but that in its immediate neighborhood there was a zone of very much congested, darker hepatic tissue. The interior of the abscess was found to consist of several

subdivisions, resembling in coarse structure the microscopic appearance of carcinoma, namely, alveola; spaces filled with pure, creamy pus (nowhere bile-stained), and the walls of the alveoli made up of trabeculae of tough, dense, fibrous tissue. The alveoli varied in size and shape. The same condition was found in the smaller abscess, but less marked. No other abscesses were found in the liver. During the examination pus welled out of the portal vein. On careful examination of the portal vein no thrombus or embolus was found; the walls of the vein were smooth, shining, and not injected.

The intestines were removed from below upwards. The appendix vermiformis was firmly bound down to the peritonæum of the iliac fossa, but no evidences of inflammation were seen. As soon as the appendix was touched it was evident that it contained some solid body, suggesting a pin, needle, or fish bone. Great care was exercised in removing the intestines, and after removal the appendix was opened by using a pair of blunt-pointed scissors. There was no perforation of the appendix, which very closely resembled a miniature glove-finger, with quite a blunt distal termination. After opening the appendix for a short distance some difficulty was experienced in advancing the points of the scissors, and some fluid, which was thick and yellow, flowed out. Pus? When laid open to its blind extremity there was found a pin lying longitudinally, with its point towards the cæcum. The pin was much corroded, its point invaginated beneath the mucous membrane for quite one half of its length. The mucous membrane of the appendix was markedly thickened, its surface elevated above the surrounding parts, with a very dark color in that portion in immediate contact with the pin; there were also many minute dark spots dotted here and there throughout the rest of the mucous membrane. There were no evidences of thrombosis in any of the mesenteric veins, which were somewhat more injected than normal. Mesenteric glands plainly visible, but not enlarged. The pelvic organs were not removed. The bladder was seen considerably distended, filling up the greater part of the pelvic cavity.

Head not examined.

Among the interstitial inflammatory affections of the liver, Orth says "that purulent inflammation appearing in the form of abscesses is rare." When observed in temperate climates it is most frequently dependent upon ulceration and perforation of the vermiform appendix (typhlitis), or purulent inflammation in surrounding tissues (perityphlitis). So far as I am aware there is but one recorded observation where hepatic abscess arose from a purely mechanical irritative cause existing in the appendix cæci, which was the seat of neither inflammation, ulceration, nor perforation. In the Transactions of the Pathological Society of London, Payne reports a case in St. Mary's Hospital where a woman died from what had been diagnosed as "pyæmia of internal origin." At the autopsy a black pin was found in the appendix vermiformis, its point projecting one fourth of an inch into the cæcum; its shaft was surrounded by fecal concretions. The mucous membrane was considerably thickened, otherwise it presented a normal appearance. There was no enlargement or ulceration of the mesenteric glands, neither were there coagula (thrombi) found in the mesenteric veins; in fact, no lesions could be distinguished at any spot between the apparent starting-point of dis-

ease (the appendix) and the liver, where a single large abscess was found, surrounded by softened and disintegrating hepatic tissue. So far as a post-mortem examination could discover, there was no inflammation of the portal veins. While it was natural to suppose that some relation existed between the presence of a foreign body in such a situation and abscess of the liver, so far as the report shows, there was no attempt either to disprove the accuracy of the diagnosis or trace the ætiology of the disease in the liver farther than what simple inspection might reveal. However, in justice to the observer it should be remembered that pathological-histology was not so thoroughly taught or practiced at that time (1869) as at the present day.

It is to this branch of science that we must look for aid if we would understand or observe the relation of morbid cause to effect. In many cases the mode and place of origin of pathological processes is difficult to discover, even when studied and examined in the light of a careful and painstaking post-mortem investigation. As in Payne's case, the unaided eye of the examiner could only discern diseased processes at their extreme points of origin and greatest manifestation, while the intermediate steps in their development were unknown, or at the best undiscovered. Pathologists affirm that hepatic abscess is most frequently the result of embolism or some form of thrombosis, originating in vessels distributed to the cæcum, ascending and transverse portions of the colon; although Ziemssen says that "abscess of the liver may exist when a thrombus in the primary or an embolus in the secondary pathological condition cannot be found, because they have been completely destroyed."

Pathological science teaches that thrombi forming in vessels with healthy walls are benignant, but may become malignant in character by absorbing the product of inflammatory disease within the vessel wall or circumjacent parts (as in perityphlitic abscess, etc.); that thrombi possess the power of originating disease in distant organs to which they have been transported in the blood stream, of a benignant or malignant character, according as they act in a purely mechanical manner, by arresting the blood flow to parts beyond, or in a septic manner, by exciting within the vessel where they are lodged true inflammation (phlebitis).

It further teaches that in consequence of the intimate and peculiar anatomical relation existing between the portal (or interlobular) and the hepatic (or intralobular) veins there may be a transference of inflammatory processes from the former to the latter, whereby new foci of infection are established for a farther dissemination of disease throughout the pulmonary circuit.

Pathological histology has demonstrated that hepatic abscesses of pyæmic origin are small, multiple, and disseminated; that the liver cells are the parts first affected, either by atrophy, infiltration, or granular disintegration, while other parts of the organ may remain comparatively normal or become secondarily affected. Single large purulent deposits are rarely if ever found in the liver associated with pyæmia, while, on the other hand, they are frequently the result of disease originating within a vessel. In pylo-phlebitis, the wall of the affected vessel is greatly thickened from proliferation of the connective tissue cells, so that the true liver cells lose their hexagonal contour from pressure, and assume irregular shapes, but remain unaffected except at the point of abscess formation, where they are com-

pletely destroyed. When the hepatic vessels are affected by inflammatory disease transmitted from the portal, their walls are thickened, the lumen greatly increased, and the vessels are filled with thrombi in different stages of disintegration, or abundance of pus corpuscles, which being mingled with the blood of the inferior vena cava, are poured into the right side of the heart, from thence to the lungs, where they may give rise to infarctions, embolic abscess, or true embolic pneumonia.

The opportunity to examine a more unique case than the present is rarely presented. The microscopic examination of various organs afforded an admirable opportunity to verify the teachings of pathology, and observe many of the intermediate steps in the development of the fatal disease.

Sections from the liver in the vicinity of the abscess and through the abscess wall showed the liver cells unaffected but greatly distorted, from pressure, so much so as to appear like columnar epithelium; the walls of the portal and hepatic veins were greatly thickened, and the calibre of the latter much increased, while both systems of vessels were filled with granular detritus, pus corpuscles, and thrombi in various stages of disintegration. Sections from the affected portions of the lung showed the alveoli filled with granular matter, while the vessels containing the emboli were apparently unaffected. Thrombi were found in the vessels leading to the affected portions, but without the radius of the diseased area. Examination of the kidney showed casts in abundance within the uriniferous tubules, but few perceptible changes in the cortex or interstitial tissue.

The case seems, from the pathological conditions observed, to have been one of phlebitic rather than of pyæmic origin. It is of interest to determine the exact spot where inflammation originated, whether at the point where the pin was found or within the liver. It certainly would seem to be a just conclusion that it arose at the point of greatest mechanical irritation, where thrombi were formed from pressure exerted by the swollen mucous membrane, and later rendered septic by the absorption of pus. Yet it certainly would seem reasonable to suppose that the parts about the appendix would have shown greater evidence of inflammation. The disturbance in the kidneys, doubtless, was of an irritative character, from the passage of the biliary salts producing congestion.

The case is particularly instructive in its clinical features, as showing how grave and fatal a disease may exist within the liver and other organs unattended by pain or soreness, the two earliest symptoms thought to be of greatest diagnostic value. Also as showing how a purely local irritative cause may originate disease of a benignant character which later may become malignant. It is noticeable that in the present case there were no inflammatory processes in the neighborhood of the cæcum which could occasion any severe symptoms during life, hence differing from the class of cases described as typhilitis or perityphilitis; that there was no perforation or peritonitis; that in the absence of local symptoms the diagnosis could not at the best have reached a greater precision than to infer the existence of some pyæmic or phlebitic process from some internal cause. It is therefore probable that other cases described as pyæmic of internal origin, and unconfirmed by post-mortem and microscopic examination, may have a similar origin.

N. B. It was not known that the child had swallowed a pin until it was shown to the parents after autopsy, when her sister said she remembered when it happened, but had quite forgotten the occurrence. According to the latter's statement the pin was swallowed about the middle of August, and the fatal illness began November 10, 1882.

A PHYSIOLOGICAL METHOD OF TREATING CARIES OF THE DORSAL VERTEBRÆ.

BY CHARLES F. STILLMAN, M. S., M. D., NEW YORK,
Orthopædic Surgeon to the New York Infant Asylum.

CARIES of the vertebræ is recognized as occurring most frequently in the dorsal region,¹ and it is also considered the most difficult to cure in this region² by any of the methods in vogue.

If simple *fixation* braces be used, such as Davis's, Washburn's, Knight's, or Shaffer's, there is not sufficient backward traction produced to relieve the diseased bodies of the vertebræ from weight, nor is there forward pressure produced about the seat of the disease to combat deformity.

If *symmetrical extension* is desired, and the plaster jacket is used for this purpose, the jury must will be required in addition, if the disease be in the middle or upper dorsal region, and the apparatus is cumbersome and not adjustable.

Wyeth's or Roberts' *local extension* jackets are not available unless provided with a head rest, and are then too heavy and unmanageable for nice practice.³

Backward traction is the most convenient and useful plan of treatment which we have at command. This aims to curve the spine backward so as to relieve the bodies of the vertebræ from the superincumbent weight which is thereby transferred to the posterior processes.

There are several methods of effecting this: the use of the *plaster jacket* applied while the patient lies face downward in a hammock (Davy), or upon two bands, — pelvic and thoracic — (Halsted), constituting *one*; the *fixation braces* of Mr. E. J. Chance,⁴ of London, which is provided with pads opposite the seat of disease, from which the upper part of the metal frame is bent backward at an angle, being a *second* method; while the use of the double knuckle joint *lever brace* of Dr. C. F. Taylor,⁵ of New York, constitutes a *third*. The latter not only curves the spine backward, but by its forward leverage upon the transverse processes of the diseased vertebræ tends to reduce or prevent the deformity.

It is, however, very heavy, since its peculiar construction necessitates great strength of material, as it is so arranged as to bring an unnecessarily severe pressure upon the spine at the seat of disease, leading in some cases to excoriation.⁶ These systems of treatment have, with few exceptions, been before the profession for a sufficiently long period, and have been employed with varying degrees of success; but, on the

⁶ Orthopædic Surgery and Diseases of Joints. By Lewis A. Sayre. New York. D. Appleton & Co. 1883. Page 483.

whole, the mechanical treatment of Pott's disease is considered to be in an unsettled and unsatisfactory condition.

In the consideration of the mechanical problem presented by this disease there are two requisites which must enter for successful treatment:—

- (1.) Arrest of the disease.
- (2.) Improvement of the deformity.

And as a result of research in this direction a new form of lever brace is proposed which is adapted to meet these requirements.

Its objects are (1) to produce extension of the bodies of the vertebræ by backward traction, thus aiming at the arrest of the disease; and (2) to exert forward pressure at the seat of deformity, thus tending to its improvement or obliteration. These objects are also embraced by the instrument of Dr. Taylor, but in the brace to be described they are attained by a different construction and by a more economical application of forces which entails special advantages.

To properly understand the principle upon which the new brace is constructed we take a patient with Pott's disease, having a well-defined knuckle, and lay him upon the back on a table, the edge of which comes to the apex of its deformity, as in Fig. 1, his

FIG. 1. Extension of bodies of vertebræ by backward traction.

head and shoulders being allowed to fall downward. This is effected by the law of gravitation, and the weight of the part of the body above the site of the disease is thus utilized to produce an *extension* of the bodies of the spine at the knuckle. The edge of the table (which, of course, should be so padded as to bring the pressure upon the transverse, and not the spinous, processes) presses upon the deformity to such an extent as to improve the form of the knuckle, and this partially or entirely disappears until the erect position is again assumed, unless the consolidation process has proceeded to such an extent as to render effort in this direction futile. See Fig. 1.

We have thus by this position produced the two mechanical effects upon the spine which we have already stated were necessary to the successful treatment of the disease, and if this position could be kept up indefinitely there would be a rapid improvement; but it is not feasible to keep the patient in this position, and we are therefore led to embody in a brace the forces which will produce and sustain this condition of the spine in whatever position the body may assume.

To do this we construct the brace in two parts,—one to represent the table and the other the backward traction power,—which in the position just shown is exerted by the attraction of gravitation.

The table part of the brace consists of a firm pelvic band, from which strong padded strips pass upward on either side of the median line to the seat of disease. See Fig. 2. The backward traction part consists of a back frame, secured on the pelvic girth by a ratchet, which admits of its adjustment at any angle with the table part of the brace, and thus regulates the degree

of traction power, which may by it be varied from a simple upright support to a powerful lever, depending only on the angle at which this back frame is thrown out and secured. (Fig. 3.) The upper part of this

FIG. 2.

FIG. 3.

backward traction frame is secured to the body by padded straps connected to a chest plate in front, to avoid constriction, and when bound down to the body, as in Fig. 4, presents the appearance there shown.

FIG. 4.

FIG. 5.

We thus perceive that by means of the two parts of this brace we can obtain the attributes desired in an effective dorsal apparatus, its mechanical action being shown in Fig. 5, by which it will be seen that after the traction frame, F P, is securely fastened at F at an angle with the table frame, F R, and the whole firmly fastened to the body, the forward tendency of the part of the body above the seat of disease would be combatted by the pads at R, and this forward tendency would at the same time act to force in the knuckle by pressure over the transverse processes of the diseased vertebræ, so that we would have a corrective automatic effect produced by the brace to keep the body erect, and at the same time improve the deformity.

Also that the spring effect produced by the setting off of the traction frame and drawing the body backward against it would cause the brace to be held more tightly against the back, and also produce the highest degree of fixation of the spine of which any brace is

capable. In the beginning of the treatment in a severe case, it is well to have the traction frame set off at such an angle as to cause considerable pressure upon the sides of the knuckle; but this angle may be lessened week by week as the patient improves, until finally the traction frame lies directly upon the pads, and becomes a mere fixation brace or support without any leverage whatever. If the case be slight or of recent date, the angle of the traction frame need be but a slight one; and as the instrument is an antero-posterior brace in the truest sense, it may be included in the commendatory remarks of Professor Shaffer,¹ who summarizes among the principal advantages of the antero-posterior support:—

"(1.) The ease with which it can be adjusted and the great comfort experienced by patients who wear it.

"(2.) It can be removed with safety at any time by placing the patient in the prone position, when such modifications can be made as are necessary to the comfort of the patient or the treatment of the case.

"(3.) The concentration of the requisite pressure at suitable and convenient points without interfering with transpiration or respiration; and, finally, the cleanliness and lightness of the whole apparatus, matters which certainly ought to be consulted in a long and necessarily tedious treatment."

POISONOUS MUSHROOMS.²

BY JULIUS A. PALMER, JR.

FREQUENT inquiry as to the best text-book on the subject of esculent and poisonous fungi leads us to notice here the two works whose titles are given in the note.

The work of Cordier is by far the most complete and of the most practical use of any yet published; while the more recent contribution to this branch of science made by Sicard contains evidence of the most patient research on the subject of the reproduction of fungi, a problem difficult of solution even by those best acquainted with this branch of the kingdom of nature.

Both attempt to pronounce upon the qualities of each species, and in that they differ from any current English work. The labors of Cooke and Berkeley are chiefly devoted to a proper classification, while those of Badham, Smith, and Hussey are too limited in their scope to be considered as text-books.

In January, 1879, the present writer contributed to the *Moniteur Scientifique*, of Paris, an article on the peculiar poison of the *Amanita* family, which article was copied and commented upon by some American medical journals. Nothing in either of these works would controvert its conclusions, which may be briefly restated as follows: Mushrooms are unfit for food by decay or other cause, producing simply a disagreement with the system, by containing some bitter, acrid, or slimy element, or by the presence of a wonderful and dangerous alkaloid, which is absorbed in the intestinal canal. This alkaloid, so far as known, is found only in the *Amanita* family, and any child can learn to rec-

ognize and reject this whole family by certain distinguishing marks, the most important of which is the volva or cup at the base of the stem.

Several attempts have been made, and not very successfully, to isolate this alkaloid; among these may be mentioned that of Schmidberg and Koppe, who obtained a colorless alkaloid to which they gave the name of muscarine; of Boudier, who, using the *Amanita bulbosa*, gave to his extract the name of bulbosine.

Mr. Sicard gives the following comparatively recent and additional testimony to the presence of the same alkaloid in another member of the *Amanita* family:—

"In 1868 Doctors Curie and Vigier sought to isolate the alkaloid of poisonous mushrooms. They used exclusively the *Amanita mappa*, because this seemed to them the most poisonous. Dr. Vigier has given to this *Amanita* two pharmaceutical forms: First, an alcoholic extract prepared by leaving for a fortnight in contact one kilogramme of fresh poisonous mushrooms crushed and one kilogramme of alcohol ninety per cent. proof. The mixture is then pressed and filtered. This tincture is given in doses of four to six grammes a day in certain catarrhal affections. Second, in the form of pills of five centigrammes of extract resulting from the distillation of the alcoholic mixture. These pills are taken in doses of three or four a day. Dr. Curie will soon publish the results of his therapeutic researches on this subject."

The use of this alkaloid as a remedial agent has long been considered favorably, and has, perhaps, made little progress chiefly on account of the difficulty of identification of species, since to the novice all toadstools look alike.

The *Amanita muscarius* (common in New England) has also been successfully employed in the treatment of chronic catarrh, profuse perspiration, skin diseases, and epilepsy.

Dr. Curtis, of South Carolina, has proposed to use the *Amanita phalloides* as a specific for cholera, Bright's disease, and intermittent fevers. His experiments were not sufficiently extended to be conclusive, but Mr. Cordier considers them worthy of repetition, and adds: "Why should not the narcotic properties of this mushroom render it a substitute for opium? It would have an advantage in the matter of its cost, for it asks for no culture. There are few wooded districts where it is not found abundantly."

There are other fungi whose peculiar properties have made them active medicinal agents so far as tested; among these the acrid milk mushrooms have been prescribed with success in phthisis, even in its more advanced stages.

But it may be noted that the authorities cited above, to which I would add my modest testimony, all recognize the *Amanita* alkaloid as the best defined of any of the toxic properties of the fungi. All these varieties are common to our woods at certain periods of the year after heavy rains. If any member of the medical profession should wish to test their properties, I should be only too happy to identify them for his experiments.

While recognizing the great value of both these contributions to a branch of science yet imperfectly understood, I regret to note very little progress in defining the action of the *Amanita* alkaloid, or in the more important matter of the treatment of a case of poisoning by such. Both of these writers advise only means

² Les Champignons. Histoire, Description, Culture, Usages, etc. Par F. S. Cordier. Orné de Vignettes et de 60 Chromolithographies. Paris: J. Rothschild, Editeur. 1876.

Histoire Naturelle des Champignons Comestibles et Vénéneux. Par G. Sicard, ouvrage accompagné de 75 Planches Coloriées. Paris: Librairie Ch. Delagrave. 1883.

such as would readily be suggested to any person of sense, namely, the evacuation of the stomach and alvine canal by means of emetics and purgatives; very appropriate treatment, without doubt, in case of the ingestion of some nauseous, acrid, or indigestible element, but not otherwise. For in the first place, to quote the language of Mr. Cordier, and Mr. Sicard uses nearly the same words: "Ordinarily four, six, twelve hours, and often still more time passes before the first symptoms are manifest. And many persons have found their death who have eaten but a single piece of the stem of an Amanita."

In the article sent by me to the *Moniteur* in 1878 occurs the following language:—

"It would appear that the amanitine is introduced into the system by absorption by the vessels of the intestinal canal, so that if one could succeed in removing every vestige of the poisonous mushrooms from the patient, it is not at all proven that he could recover."

Mr. Sicard seems to hint at a similar conviction, for he says:—

"Naturally, I have sought oftentimes to arrest abruptly (*enrayer*) the toxic effects in introducing into the mouth of dogs, poisoned by design, fifteen centigrammes of mineral turbinth to provoke vomiting, and in making them take a great quantity of syrup of buckthorn. When the toxic substance was absorbed they were allowed to die — ('on les laissait mourir'). Recently I have sought an appropriate antidote; an antidote of which the effects after absorption should be diametrically opposed in the system to those produced by the alkaloid of the mushroom, defined as an acrid and stupefying poison. I have made, by means of the syringe of Pravaz, at first under the skin in the middle of the back an injection of two milligrammes of nitrate of pilocarpine. Half an hour after I gave a second injection with the same dose, but this time a little to the left of the heart. Fifteen minutes later, under the influence of such a sudorific agent, a feeble return of heat could be detected at the surface of the skin, which was encouraged by straw friction. As soon as possible, the animal was made to drink five grammes of nitrate of potash dissolved in one hundred grammes of dilution of marsh-mallows. With the aid of these means the pupil of the eye became sensitive and contracted, thus showing a change in the symptoms. In strict truth, however, I must say that the dog never returned to his normal condition, but the progress of the poison ceased, and he at least lived."

The above experiment is of value because suggesting a new element with which the physician may combat the effects of the poison after its absorption into the system by the patient. This absorption may take place not only by ingestion but by contact with the skin, as through the hollow palm of the hand, or even by the lungs, as I have proven by personal experiments made upon myself. In such a case the patient has all the symptoms of having eaten of the mushrooms, even to a peculiar leaden or ash-colored complexion.

This article would be incomplete if it failed to add that the remedy in such cases seems to be found in the skillful use of the alkaloids obtained from the *Solanaceæ*, or night-shade family, especially in the hypodermic injection of atropine. The physician may readily infer that any person who, from six to eighteen hours after eating mushrooms, has symptoms not varying widely from those indicated in cholera, is under the influence

of Amanita poison, and he must take action accordingly. The shorter the time between a meal on mushrooms and the appearance of any unfavorable symptoms, the less occasion to dread fatal consequences. So far as known the Amanita is the only mushroom which has proved fatal to human life.

REPORT ON PROGRESS IN THERAPEUTICS.

BY FRANCIS H. WILLIAMS, M. D.

THE USE OF IODINE AS A STOMACHIC SEDATIVE.

DR. GAUNT, of New York,¹ gives an account of a very extensive use of iodine for the relief of various forms of vomiting, and cites cases where he has used it in the vomiting of pregnancy, phthisis, and hysteria, in hard drinkers, in septicæmia, chronic nephritis, and in acute catarrhal gastritis, and refers to one hundred cases of gastro-intestinal disturbance accompanied by vomiting. One to five drops of the compound tincture of iodine in water, in frequently repeated doses, were used.

In some five hundred cases of gastro-intestinal troubles, treated during last summer, not a single case was lost. Iodine was given whenever vomiting threatened, and in the case of children the milk was boiled just before being taken, and diluted with lime-water. No attempt is made to explain the influence of iodine in small, frequently-repeated doses over the symptom of vomiting.

In case mucus is present in large quantities, washing it out with an alkaline solution, by means of a stomach-tube, before giving the iodine is suggested. It is well also to bear in mind the power possessed by starch in annulling the action of iodine.

The following is suggested as the best way to give the drug:—

R Tincture iodinii comp.	Mviii.—3 ss.
Bismuthi subnitrat	3i.—3i.
Glycerinæ	
Aq. cinnamomi }	aa 3ij.
Liquoris calcis	ad 3ij.
M. et sig. Dose one dessertspoonful.	

Or, better, as the above will keep only twelve hours, have the mixture put up without the iodine, and add that from a separate bottle immediately before administration.

CONVALLARIA MAJALIS.

This is one of several drugs which have been proposed as substitutes for digitalis. It was used more than one hundred years ago, has been forgotten, and again brought to notice of late years chiefly by Professor Sée, of Paris. He recommends it in palpitation of the heart, in cardiac dilatation, fatty degeneration, and also in valvular lesions with failing heart power, or, in general, in such conditions as digitalis would be found serviceable.

In this country Dr. Taylor, who published² the results of seventy cases at the Roosevelt Hospital, thought that the results obtained were as good as with digitalis.

Dr. Beverly Robinson,³ after an experience with a considerable number of cases in which convallaria was used, concluded that we have in digitalis the most

¹ American Journal Medical Sciences, April, 1880.

² Medical Record, January 27, 1883.

³ Medical Record, December 9, 1882.

efficient heart regulator and tonic yet known. No cumulative action was noticed with the convallaria.

The experience of Stiller¹ gave seventeen negative results out of twenty cases. The preparation used by him may not have been a good one.

Dr. Pels² gives a very careful and full account of the trials which he and many others have made of this substance. His conclusions are: that the aqueous extract, even in large doses, has no injurious action, at most it only promotes the movement of the bowels; as a heart tonic and diuretic it is inactive with a weak left ventricle, particularly that associated with chronic nephritis; on the other hand, in some cases of organic disease, especially mitral insufficiency without compensation, it has a stimulating and diuretic effect, but even here the action of digitalis is more marked, and of longer duration; finally, although the lily of the valley, compared with digitalis, gives rise to no dangerous symptoms, it does not equal it in efficiency. In urgent cases convallaria is not to be thought of, but digitalis should be used.

POISONING BY ILLUMINATING GAS SUCCESSFULLY TREATED BY THE INHALATION OF OXYGEN.

Dr. Alonzo Clark reports the cases of a woman forty years old, and her daughter of twelve years, who had been exposed for fifteen hours in a room filled with illuminating gas. The mother was found to be suffering from pulmonary oedema; the radial pulse was scarcely perceptible; she was unconscious and cyanotic; her extremities were cold; there was trismus with rigidity of the flexor muscles; the urine was passed involuntarily; the pupils were slightly contracted, and a frothy mucus issued from the mouth; her temperature was 96.5° F., and her respiration 40.

Inhalation of oxygen was kept up for three hours. In addition dry cups were applied over the chest, and tincture of digitalis was given endermically, in all to the amount of thirty minims. Whiskey was also given subcutaneously, and hot-water bottles were applied to the extremities. Occasionally, too, the patient was aroused by flagellation.

This treatment extended over a period of four hours, at the end of which time the woman began to show signs of returning consciousness; the pulse became more perceptible and regular, warmth returned to the extremities, and the temperature and the respiration were found to be normal. The next day the patient was able to tell her own story, and was soon afterwards discharged. The treatment of the other case was the same, except that in addition a hypodermic injection of a sixtieth of a grain of sulphate of atropine was given. This patient also recovered.

KAIRIN, A NEW ANTIPYRETIC.

A short account of the discovery of this drug by Dr. Fischer, and its use in medicine by Dr. Filehne, was given in this journal last year.³

The action of the medicine begins about half an hour after being ingested, the fall in temperature being more abrupt the larger the dose. In every case the fall in temperature is accompanied by free perspiration, which continues only while the temperature is falling;

as soon as the lowest point has been reached, which occurs after from two to four doses, diaphoresis ceases, and the temperature remains constant so long as one chooses to give kairin. During the diaphoresis, as well as after it, the patients are much relieved, especially those suffering from acute pneumonia; in this disease not only is the temperature reduced, but the pulse and respirations are made much less frequent; the pulse is strengthened, and the pleuritic pain lessened, by this drug. As soon as it is omitted for two or three hours, according to the size of the last dose, the symptoms return as before, the temperature rises to the height characteristic of the disease, and is accompanied by a chill.

In a later article Dr. Filehne says that kairin has been found of great value in a variety of chronic and acute diseases. In special cases, however, its application requires that the temperature be minutely observed during the first day. The following scheme of using kairin with adults has been worked out by him: In the first instance kairin is administered in separate doses of 0.25 gramme each, taken in wafers, and an ample quantity of water drunk after them. It is advisable to commence with doses of 0.5 gramme per hour on the first day, and to give these say four times successively, but no longer than until the temperature has reached 38° C. (about 100° F.). The temperature has to be observed once every two hours, or if possible every hour, during the first day; later on this is not necessary with the same individual. When the temperature has been lowered by the above doses to about 38° C. only 0.25 gramme is given per hour, and this is continued until the temperature is rising perceptibly, when the former dose of 0.5 gramme should once more be administered. A dose of 0.5 gramme has to be given at once if the patient feels the least chilliness. Should it be that 0.5 gramme per hour have not had the desired antipyretic effect after four administrations, doses of one gramme are given two, three, or four times at intervals of an hour. When, on the other hand, the action of 0.5 gramme per hour was perceptible after four hours without proving sufficient, 0.75 gramme is given about four times at intervals of an hour. The doses of one or 0.75 gramme per hour are stopped when a temperature of 38° C. is reached, keeping a reserve dose of 1.00 or 0.75 gramme respectively in readiness, which is to be taken at once should the patient feel the least chilliness. When the temperature has again risen the administration is started anew.

Since the organism neither gets accustomed to the medicament nor shows a cumulative effect from kairin, a careful day's experimenting in the way indicated suffices, and the dosing thus standardized on the first day may afterwards be adhered to.

When the weight of the body or the condition of nourishment is excessively low, and in cases of hectic fever, smaller doses have often to be tried first.

In intermittent fever⁴ the temperature may be lowered, but very large and frequent doses are required to keep it down, and they may give rise to unpleasant symptoms. It may be used subcutaneously, but not too often in the same locality.

On the other hand, Seifert⁵ did not find its action so good in all cases. In two cases of severe pneumonia,

⁴ Centralblatt f. d. gesammte Therapie, June, 1883.

⁵ Centralblatt f. d. gesammte Therapie, June, 1883, Untersuch. u. d. Wirkungs weise einigen neuer arzneimittel.

doses of 0.75 gramme every two hours effected no change in the temperature or pulse; in both it caused vomiting. In another case the temperature was reduced, but the patient became collapsed, and died.

The writer has given the drug to a few children and observed no unpleasant symptoms. In one child, three years old, 0.2 every hour for five hours was without effect on the temperature, which was taken hourly; 0.2, 0.3, 0.4 gramme at intervals of an hour brought down the temperature from 40° C. to 38° C. (104° F. to 100.3° F.). In a child of eighteen months four hourly doses of 0.2 gramme changed the temperature from 40.7° C. to 39° C. (105.1° F. to 102.1° F.), and again, in the same case, 0.3, 0.4, 0.5 gramme at intervals of an hour brought the temperature from 38.9° C. to 37° C. (102° F. to 98.6° F.).

A very limited experience with adults suggests that the drug will be found to have too many disadvantages, or, rather, inconveniences to ever become very popular, although as the forerunner of a more perfect antipyretic, which we may look for in the near future, it is of interest.

NITRITE OF SODIUM IN THE TREATMENT OF ANGINA PECTORIS.

Dr. Mathew Hay¹ has recently made careful clinical trials of this salt in well-marked cases of angina pectoris. In one case nitrite of amyl was inhaled from three minim capsules six or seven times a day for about a week with good results. The nitrite did not entirely dispel the pain, it merely dulled it, and was always accompanied by giddiness, which compelled the patient to remain quiet for a minute or two, and it was followed by a headache and disagreeable feeling, which lasted one or two hours.

On the theory that the action of this drug is largely due to the nitrous acid it contains, as shown by the experiments of Reichert and Weir Mitchell,² nitrite of sodium was tried:—

R. Sodii nitritis 3 ss.
Aquam ad ꝑ 3 xii.
Solve. Sig. Dose, one to two teaspoonfuls.

After a week the patient reported that he took a dose in the morning; this enabled him to get up, dress, breakfast, and walk to his office without experiencing the slightest pain, and without requiring more of the nitrite until after dinner; then it was taken only when he felt the pain coming on, and if he took it promptly it caused complete cessation of the pain in from one to two minutes. Nitrite of amyl had never completely abolished the pain. The nitrite of sodium caused no perceptible throbbing in any part of the body, and certainly no headache; apart from the effect on the pain it seemed to have no more action than so much water. In addition to the morning and noon doses he took one before going home at night, and at bed-time, as well as during the night if the pain came on. After three weeks it was found that whenever the nitrite of sodium was omitted he was liable to attacks of pain. If he took no medicine in the morning he never failed to have an attack of pain when he began to dress himself, and another on his way to his work.

It was found by comparison that the preventive action of the nitrite of sodium is exercised over a much longer period of time than that of nitrite of amyl, and

that the nitrite of sodium acts in two or three minutes, or more slowly than the nitrite of amyl.

Instead of the nitrite of sodium one or two teaspoonfuls of a one per cent. solution of nitro-glycerine was tried; its action was found to be similar to, though better than, the nitrite of amyl, but its effect did not continue as long as the nitrite of sodium.

Dr. Hay anticipates a wide and important application in various forms of disease of the simple and more safely administrable nitrites.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

CHARLES H. WILLIAMS, M. D., SECRETARY.

JUNE 4, 1883. DR. E. H. BRADFORD read a paper on

SEVERE CASES OF CLUB-FOOT.

He called attention to the need of improved methods of treatment, and to the fact that failure was often the result of bad method rather than from want of care on the part of the surgeon or nurse. The general plan has been to do a tenotomy, then send the patient to the instrument maker for a Scarpa's shoe or other apparatus in which the foot was daily straightened by straps until it was considered ready to wear some form of ankle support. What is needed is simplicity in detail; the foot should be forcibly placed in an overcorrected position, by the hand or some mechanical appliance, and tenotomy, with division of the plantar fascia, should be done if necessary; the foot should then be fixed in this position, and finally a walking shoe should be provided of such simple construction that the mother can look after it. The osteoclast has shown that great pressure can be used on the skin without serious result, and an instrument was devised by the reader with which he was able to reduce deformities of the foot which would not yield to hand force. The instrument consists of a steel plate, to the sides of which three screws are attached in such a position that their padded and broadened ends bear on the inner side of the heel, the ball of the great toe, and the outer side of the astragalus; a padded plate is fixed over the foot to keep the sole pressed down on the bed plate of the instrument; by turning up the screws the deformity can be reduced.

It may not be possible to correct the position of the foot in one sitting; in one case with great deformity, in which the apparatus was used, it was necessary to have three trials before a good result was obtained.

In order to hold the foot in good position after correction, a plaster of Paris bandage is used, and if this is applied properly the danger of sloughs is very small; the bandage should always be put on after the foot has been placed in its new position. The foot and leg are first covered with a thin layer of cotton batting; then, the foot being held by an assistant, either in his hands or by means of one or two wide strips of adhesive plaster passed round the foot, the bandage is quickly applied, and must be carried above the knee to prevent the turning of the foot. After wearing this bandage some two or three weeks it is removed, and a steel splint is substituted, which is arranged with a joint at the ankle and a sole plate, to which the foot is attached by a bandage. After keeping the child in

¹ Practitioner, March and May, 1883.

² American Journal Medical Sciences, 1882, vol. lxxx.

such an apparatus for three or four weeks, it is best to have a walking shoe made, so that the muscles of the leg may get their normal balance. The ankle support, as usually worn, does not prevent the turning in of the foot, and this is best avoided by means of a thin metallic sole, corresponding in shape to the bottom of the foot; this is attached to a rod which is fastened to the leg higher up. The whole apparatus can be worn inside the ordinary shoe; it is light, and effectually prevents the turning in of the toes. In cases where the deformity is slight, it can often be corrected by the use of the walking shoe, without tenotomy.

DR. A. T. CABOT thought that the danger of sloughing had prevented many surgeons from trying this method, and that the reason why the reported cases had been so free from this accident was that the position of the foot had not been overcorrected before applying the plaster bandage. In one case of talipes varus Dr. Cabot had put on such a bandage, but was obliged to remove it on the second day on account of a threatened slough. In the treatment of talipes equinus, where the contraction of the tendo-Achillis is very great, there might be a danger of imperfect union of the tendon when put up in such an apparatus after a tenotomy; in such cases a more gradual method seems to be indicated.

DR. R. M. HODGES spoke of the unsatisfactory method of treatment usually followed in general hospitals; the cases cannot be treated in the out-patient service of a hospital on account of the time needed. The novel apparatus and methods shown by the reader show how much can now be accomplished in a few days which formerly required months.

DR. BRADFORD said that the forcible means spoken of involving the use of an apparatus with screws was not to be used in the simple cases. The danger of non-union of the tendo-Achillis is very slight; in one of his earlier cases there was some turning of the foot, owing to not carrying the plaster bandage above the knee. In one case a small sessile aneurism was formed on the posterior tibial artery, the result of a prick with the tenotome. It disappeared, however, on tying the origin of the aneurism. In answer to the question at what age a child could be operated upon for club-foot, the reader thought the earlier the better. He had had a patient only eight weeks old. As to correcting the deformity by an operation or by slower methods, that depends entirely on the wishes of the parents; if they desire a quick recovery there is no objection to operating. In very young children more care must be taken in applying the plaster bandage, in order to prevent chafing. The wetting with urine can be avoided by painting the bandage with some waterproof material. In reply to Dr. Hodges, he said that in correcting talipes he cut the plantar fascia first, then the tendo-Achillis. He had had one patient with a gap of one and a half inches in the tendon after the operation which had recovered with complete union.

— A correspondent asks for the experience of the profession concerning the digestibility of the lobster, particularly with reference to the point whether the common opinion is correct that that fish should be avoided by all except the strongest stomachs. Also with regard to the comparative digestibility of different portions of the fish, and whether any part is actually injurious.

Recent Literature.

A Treatise on Therapeutics, comprising *Materia Medica* and *Toxicology*, with Especial Reference to the Application of the Physiological Action of Drugs to Clinical Medicine. By H. C. WOOD, M. D., Professor of *Materia Medica* and *Therapeutics* in the University of Pennsylvania. Fifth edition. 740 pages. Philadelphia: J. B. Lippincott & Co. 1883.

Of a work so well known little need be said about this last edition. It is fully abreast of the latest and best in this department of medicine, and although not much new matter has been added, the article on *Convallaria Majalis* is typical of the author's intention to include whatever promises to be of value if its claims seem to be well founded.

An interval of only six months between the last two editions, and the excellence of both, suggests that the profession appreciate the philosophical methods and scientific spirit pervading this standard work, which still retains the first place among all our treatises on this subject.

THE RISKS OF MASSAGE.

DR. JULIUS ALTHAUS, in the *British Medical Journal*, deprecates the indiscriminate employment of massage as capable sometimes of producing disastrous results. He says:—

"It is well known that at various times epilepsy, idiocy, and some forms of insanity have been treated by massage and gymnastics; but, fortunately, we now hear very little of such therapeutical aberrations.

"It appears to me that diseases of the brain and spinal cord must, on account of the anatomical situation of these organs, be inaccessible to the influence of massage, which can only be applicable to more superficial parts of the body. Apart from this, however, it is important to consider that many of the most important diseases of these organs are of an inflammatory or irritant character, either primarily or secondarily; and this should make it self-evident that massage should not be used for their treatment, even if the suffering parts could be reached by it. I will here only allude to many forms of cerebral paralysis from hæmorrhage, embolism, and thrombosis, which are followed by sclerosing myelitis of the pyramidal strands; and most forms of primary lateral, posterior, or insular sclerosis of the spinal cord.

"That which may be good for developing and strengthening healthy muscles, or muscles which have been enfeebled by disuse or certain local morbid conditions, etc., is not for that reason suitable for the treatment of muscular paralysis owing to central disease. In most cases of lateral and insular sclerosis, which are, unfortunately, now much treated with massage and exercises, rest is indicated rather than active exertion; and overstraining of the enfeebled muscles acts prejudicially on the state of the nervous centres. I have recently seen quite a number of instances in which the central disease had been rendered palpably worse by procedures of this kind; and in a case of cerebral paralysis which was some time ago under my care the patient had, after four such sittings, been seized with collapse, which nearly carried him off."

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 20, 1883.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, Boston. Price, 15 cents a number; \$5.00 a year, including postage.

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE CORONERS MUST GO.

THERE are many indications that the race of coroners in this country is destined to be exterminated. The process of eradication may be slow in some regions, but the signs are clear that it is certainly in progress. The antiquated jury method of investigating violent deaths is suffering from a senile gangrene which renders it highly offensive. Ever since legislative action in Massachusetts, in 1877, initiated rational treatment, and pointed the way to an improvement in this department of the public service, the American coroner's fate has been sealed. The medical examiner system, which has been in successful operation for six years in this State, is no longer on trial as an experiment. It is sufficiently recognized here as one of the most fortunate reforms which the Commonwealth ever accomplished. It has been watched with keen interest by those who originated it, by those in later sympathy with it, and by those who thought they had little reason to bestow their favor upon it; and it is truly remarkable that scarcely a word of adverse criticism has been elicited in all the six years of its existence. It has been found to fulfill its mission quietly, effectively, and economically.

It is not extraordinary, therefore, that sagacious men in other communities, observing these results, have been stimulated to attempt the substitution of the medical examiner for the coroner through legislative enactment. From States even remotely situated, like Kentucky and Louisiana, inquiries have come concerning the practical working of the Massachusetts plan. Much interest has been manifested in Philadelphia with regard to the matter; while in the neighboring States, Rhode Island, Connecticut, and New York, more zealous efforts have been made to effect the desired change, and the views and wishes of the advocates of the reform in those States have been formulated in bills, which have been submitted for legislative action. It was hardly to be expected that the statute of Massachusetts would be adopted in all its details in other localities; hence, in the bills above alluded to, while the important fundamental feature of the new departure is fully recognized, and the medical examiner entirely supplants the coroner, there are to be found many proposed modifications of the Massachusetts law, growing, undoubtedly, out of a desire to avoid too violent interference with long-established usages. Thus, in the latest of these drafts, that pre-

sented by the Newport Medical Society to the General Assembly of Rhode Island at its last session, we find some important variations from the original medical examiner statute. For example, this bill proposes that the medical examiners shall be between twenty-five and forty-five years old, and shall be elected by the legislature in general committee. Again, it provides a premium for short autopsy records as well as long ones, — one dollar for the first one hundred words or fraction of a hundred, and twenty cents for each additional hundred or fraction of a hundred." The "necessary expenses for postage, stationery, and travel" are to be paid by the State, the creditor in the matter being the interpreter of the word "necessary." The medical examiner is to examine the dead bodies of persons who "are supposed to have come to their death by illegal means [an unfortunate expression, it seems to us], or without the recent attendance of a physician in good standing," the interpretation of the words "good" and "recent" being left with those who receive the fees for the service rendered. The word "person" is defined as including "prematurely born children." One of the witnesses at an autopsy must be a physician, whose attendance may be compelled by subpoena; his fee for the service is fixed at four dollars, and his "necessary expense" is to be paid by the State. An "autopsy" is to be understood as "the inspection and examination of any or all of the internal organs," — an excellent definition if the words "any or" were omitted.

We have pointed out these proposed departures from the statutory provisions relating to inquests in vogue in Massachusetts, not with any desire to indulge in captious criticism, but rather with a wish to co-operate in perfecting a system which has great merits already tested by time. The Massachusetts law is not faultless; those who have administered it admit that in certain minor particulars some amendment is desirable; but as a piece of legal machinery for the detection of crime and the protection of public morals, it has worked with unexpected smoothness and efficiency, and we should deprecate any tinkering of its parts which would impair its usefulness. We think it would be a mistake to take the nomination of the medical examiners out of the hands of the governor, and make it an occasion for legislative squabbling and pipe-laying; or to appoint an examiner under thirty years of age, or to be debarred from appointing one over forty-five; or to pay a fee for writing an official report of an autopsy with a petty temptation to be either brief or verbose; or to offer the smallest inducement to take money from the public treasury through an inevitable elasticity in the interpretation of any words in the statute; or to discount the efficiency of the medical examiner as a medical detective of crime by diverting his specific functions into other paths of usefulness, such as certifying the cause of the death of persons who are known to have died in the course of nature but without recent medical attendance. One of the great objections to the coroners has always been that by indirect incidental perquisites they have cost too much for the service which they rendered;

any legislation which abolishes them and substitutes another system ought, by all proper and liberal provisions of a positive and well-defined character, to attract to the vacated places truly "able and discreet men," without offering to them any direct or implied opportunities to enlarge the pecuniary advantages of their office or to abuse it in any manner.

We note with satisfaction that, as in Massachusetts in former years, so now in other States the medical profession is most zealous in urging forward the reformed methods of managing inquests. We wish the friends of a good cause all possible success. It is hardly to be expected that the fortunate combination of circumstances which so signally favored the reform in Massachusetts in 1877 will again be witnessed elsewhere; but the earnest purpose and wise judgment of our neighbors will surmount all their difficulties, and accomplish the end desired. The Rhode Island Medical Society, at its meeting to-day, will have the subject as a special theme for discussion, and there can be but little doubt concerning the tone of its deliberations.

NEW YORK'S WATER SUPPLY.

THE questions connected with the water supply of large cities are interesting either directly or indirectly to a very large portion of the population. The discussions and plans of the officials connected with the water supply of the largest city of this portion of the globe are worthy of study in other quarters, and we give them without comment.

At a meeting of the new Croton Aqueduct Commission held September 12th, at New York, a number of prominent gentlemen, including Hon. Erastus Brooks and Dr. Elisha Harris, of the State Board of Health, and Prof. Charles F. Chandler, recently President of the City Board of Health, were invited to be present and discuss the proposed plan of building a large dam at Quaker Bridge. The Hon. Orlando Potter said that it was important that the commission should know how such a dam would affect the public health. The water would be drawn down fifty-eight feet every year, and the question was how to do this without injury to public health.

Dr. Harris remarked that a question of great moment was, whether the plan proposed contemplated reservoirs independent of each other, and another question was, whether or not malaria would be increased. He said that physicians had no fear whatever of deleterious water being brought to the city by the aqueduct. The Croton water had never yet made anybody ill, and all fears of anything of that sort were groundless, even when there was a little odor about the water, as occasionally happened. There was scarcely another valley in the world known to medical men so desirable for use as a source of water supply.

The commission then listened to an elaborate report from the Department of Public Works, giving additional plans, for the increase of the water supply, with special reference to a plan worked out by Chief Engineer Church to build a subsidiary dam at Mus-

coot Mountain, in order to overcome any sanitary objections which might be raised to the construction of the Quaker Bridge dam. This smaller dam would be near the upper end of the present Croton Lake, about six miles above the present Croton dam, and could be completed by the time that the new aqueduct is finished, at a cost of about \$400,000. Two important purposes would be subserved by it. Its effect on the water supply would be to form a lake of 2,500,000,000 gallons storage capacity, which, in conjunction with the present Croton Lake, would be sufficient to supply the new aqueduct with water until the Quaker Bridge dam is completed, even if the latter should occupy a longer time than is at present estimated. The second and most important effect of the Muscoot dam would be the sanitary protection it would afford to the region above the dam. During dry seasons it would be necessary to draw down the large reservoir from twenty to sixty feet, and this would inevitably lay bare many acres of land at the upper end of the reservoir, and expose a number of thickly settled towns and villages to the dangers of malaria. By the construction of this subsidiary dam, however, the whole difficulty would be obviated, for with such a dam, when the large reservoir was drawn down, the upper shoals would still remain covered, and the proper hygienic conditions be maintained. Dr. Harris and Mr. Brooks, of the State Board of Health, having carefully studied Mr. Church's plan, both expressed themselves as much pleased with it, as they believed that the lake thus formed by the Muscoot Mountain dam would do away with the objection that malaria might be spread from the shallow flats at the upper end of the large reservoir.

MEDICAL NOTES.

— At the last congress of German surgeons (*Annals of Anatomy*, September, 1883), Schönborn (of Königsberg) exhibited a specimen removed from the stomach of a girl who had suffered for two years. A tumor of the size of a fist could be felt in the gastric region, the same being painful on pressure. The diagnosis as between a tumor of the spleen or of the omentum was uncertain. Upon operation it was found to lie in the stomach, whence it was removed. Incision of the tumor showed it to consist of short hairs matted together. It afterward transpired that this girl, with a number of her schoolmates, "in order to gain a clear voice," was in the habit of biting off her hair and swallowing the ends thus bitten off. The case is not unique. Seven similar cases are recorded, one of which was complicated by a second similar mass in the intestine; but all the others ended fatally — one from hæmorrhage from the stomach, the others from peritonitis, or incurable vomiting. Some of these patients had swallowed the hairs in their full length.

— At the same meeting a case of wound of the thoracic duct was reported by Boegehold (of Berlin). He had helped his chief, Wilms, at an operation for a

large cancerous tumor of the left supra-clavicular region. During the operation he had to dissect down towards the junction of the jugular and subclavian veins. While scraping out the diseased tissue with a sharp spoon, he was astonished at a stream of milky fluid as large as a small straw being poured out over the operation field. It was checked by a tampon of salicylic cotton, after which the wound healed without reaction, while the general condition of the patient seemed in no way disturbed, and he lived for six months. No autopsy could be secured. There was not the slightest doubt as to the injury. The extreme rarity of this accident led Boegehold to study its literature. He was able to find but one authentic case, related by Bonet in his work on practical anatomy published in 1700. The patient was wounded in the breast by a bullet, and for several months a milky fluid escaped in considerable quantity from the bullet wound, while death finally was caused by inanition and paralysis.

— An English contemporary remarks that Herr E. Merck, of Darmstadt, at the instance of Professor Hegar, of Freiburg, has succeeded in producing a phosphate of codeia, which has the great merit of being soluble in four parts of water, so that it can be used subcutaneously. It crystallizes in small four-sided columns, is white, rather bitter to the taste, and resembles the sulphates and hydrochlorates of the same base. In its action it resembles morphia, except that it is milder, and the symptoms of intoxication are less pronounced. The dose required is about double that of the salts of morphia. No marked local disturbances followed the subcutaneous employment of the drug.

— A somewhat remarkable testimony was given by a medical expert at a recent trial for rape before the high court of judicature of England. The witness, who had examined both the plaintiff and the accused, stated in his written report that: "On pushing back the foreskin of the penis of the accused there was an odor perceptible peculiar to woman." He argued that this was conclusive of coitus having occurred.

— Faience is the newest vehicle of contagium which has been discovered. It seems that porous ware may become literally infiltrated with noxious matter, and may possibly be the receptacle and breeding ground of the germs of diseases. M. Constantin, who has made this discovery, says that even glazed earthenware is not free from objection, for it always contains rugosities and chinks, however minute, into which undesirable substances may enter from the fluid contained in these vases en faience. He would proscribe such glazed ware from hospitals where contagious diseases are treated. Glass and porcelain, he says, ought only to be found there.

— It is reported that Dr. Jakimovicz, of Jarvszinka, in the government of Kiew, Russia, has just died at the age of one hundred and six, and that he was able until nearly the close of his life to superintend the carrying on of an extensive practice.

— The *Medical Press* pertinently says *à propos* of physiological research and pigeon-shooting: "By a majority of nearly two to one our hereditary legisla-

tors have given another year of impunity to the cruel slaughterers of the dove. Our legislation decrees that physiological research promoted for the protection of human life is a crime to be put down by law; and most effectually have they put it down, except in the case of a few favored individuals, who work under license, and under serious restrictions. When it becomes a matter of interfering with the 'noble sportsman,' however, it is quite another affair; and the peers, headed by Lord Redesdale, have declared, as far as in them lies, that the noble sportsman is to be let alone. The current number of a fashionable contemporary records that last week a member of our nobility won three pigeon-match cups; but no record is given of the number of pigeons massacred, nor could any record be made of the mutilation and dying agonies of the hapless creatures smashed with shot as they hovered dazed above the traps in which they had been confined. Probably there was more pain and suffering to the brute creation on that occasion than would occur in the physiological laboratories of the empire in a year, and yet the law says to the investigator, 'Cease,' and to the pigeon-match competitors 'Go on.'"

The *Lancet's* comments on this subject are still more radical and outspoken. It says: "Pigeon slaughtering is precisely the sort of pastime which would commend itself to the instincts of the feeble-minded and unmanly clique of persons who formed the majority of the Upper House. As a matter of absolute fact, the only consideration which preserves the sanction of the law for pigeon-shooting is the excuse it offers for petty gambling. Anything more disgraceful than the betting which goes on at the so-called 'clubs' which assemble for the purpose of slaughtering trapped pigeons, it would be difficult to imagine. For the session this measure is lost. Next year it will be revived; and then doubtless, with the accustomed cowardice of their house when actively pressed, the peers will pass the bill. Meanwhile by its rejection they have driven another nail into their own coffin."

— A case of death from a wasp sting has recently occurred, according to the *Medical Times and Gazette*, in the person of a lady, aged fifty-five, of Mark Hall, near Harlow, who died within half an hour after receiving the sting on her little finger. At the inquest it was stated that she fainted almost immediately after being stung, and never recovered consciousness. Dr. Day deposed that death ensued from syncope, produced from excessive pain caused by the wasp sting. Some other similar cases have since been reported. We notice that a correspondent of an English journal believes that for some reason such fatal cases are especially seen in the autumnal season.

NEW YORK.

— On Friday, September 14th, Health Commissioner Raymond invited all the milk dealers of Brooklyn to meet in the Common Council chamber, when Dr. Bartley explained to them the various tests by which they can determine whether the milk they

purchase is of the required standard. After this conference, the licenses of such dealers as are detected in selling adulterated milk will be peremptorily revoked.

— A lad employed in a lawyer's office in Brooklyn during the past year became so addicted to smoking cigarettes and chewing tobacco that he recently died of narcotic poisoning.

PHILADELPHIA.

— The colleges here began their fall sessions this last week (September 10th), and have already a fair number of students in attendance. Of course bright anticipations are indulged in with regard to the size of the prospective winter's class, but whether they are fully realized or not there is, however, sufficient evidence that Philadelphia is not in immediate danger of losing its old-time prestige as a great medical centre. With regard to the preliminary course it is noticed that some of the elders have learned practical wisdom from experience, and now pay more attention to the *personnel* of the lecturers, instead of offering poor wine at the beginning of the feast, and intrusting these lectures to the hands of assistants, as too long had been the custom. Many members of the Faculty themselves now lecture to the earliest arrivals, thus securing those of doubtful mind who might be repelled by even the best efforts of a tyro even if he does rejoice in the title of Adjunct Professor.

The societies are also starting out with a rush, and the plans for a winter of active work have been to a large extent already matured. A few years has seen great changes in our College of Physicians. Under its new and progressive management, headed by Professor Stillé, a series of improvements have been inaugurated, the end of which it is feared may greatly disturb the equanimity of some of the older and more conservative Fellows. Through the generosity of a distinguished member of the Committee on the Mutter Museum a fund has been actually established for entertainment purposes, and arrangements are contemplated for giving an annual dinner, and also receptions at which ladies will be present. The introduction of the telephone, and the providing of a comfortably furnished conversation and smoking room during the past year or two, is leading (it is hinted) to the establishment of a lunch room on the premises, where Fellows may obtain some light refreshment. The Nurse Registry Bureau, also, is more than ever growing in usefulness, and promises to have a good surplus at the end of the year. The most skeptical may be convinced that a wondrous change has come over this venerable institution, by comparing its last annual volume with its immediate predecessors. New life has been infused into the organization within a few years, and as a consequence a large number of applications for membership have been handed in, and still more may be reasonably expected. The other societies, the County Medical Society, the Pathological Society, the Obstetrical, the Academy of Surgery, and the rest, all report progress and continued growth.

— As an illustration of the value of last winter's

lectures to the police force on minor surgery and early aid in emergencies, it is reported that during the month of August the police attended twenty-four cases in which surgical knowledge was necessary.

— A peculiar case occurred recently, which deserves notice from its rarity according to the best authorities (if the superintendents of insane asylums may be quoted as the best authorities upon this subject). An elderly man, Frederick Haas, being, as was afterwards testified, of a sound mind, was sent to the Norristown Insane Asylum, by order of the court, he being declared by a physician to be insane, on application by his relatives, who wished to be relieved of his support. His son, who was absent from home at the time, on returning learned with surprise, from one of the daily papers, that his father was in the asylum; he at once went to Norristown and threatened to take out a writ of habeas corpus unless his father was released. The superintendent upon being informed of this proposed action discharged the old gentleman with a certificate declaring that he was of "sound mind," although he had been confined for a week among the insane, and classed with them!

The possibility of the future repetition of the Haas case, in this State at least, will, it is believed, be effectually prevented by the new law, which went into effect on the 17th of this month. This measure provides that every doubtful case of insanity shall be promptly investigated by a commission appointed expressly for that purpose. By this means the prolonged detention in any asylum in Pennsylvania of a sane person will be effectually prevented.

Miscellany.

POSITION IN LABOR.

DR. A. DRUMMOND MACDONALD read a paper at the recent meeting of the British Medical Association on this subject, in which he took exceptions to the ordinary position in labor as practiced in Great Britain, the woman lying on the left side *with thighs flexed*. While admitting that this position is convenient for commencing obstetric operations, he advocates in terminating all, or nearly all, labors, what he terms the straight-bodied or (for the lovers of classic expression) the orthodematic position, — a right or left sided position, with the lower extremities adducted and placed as nearly as possible in the line of the body axis.

His argument is that when the thighs are flexed an artificial tension is induced by the dragging of the skin of the nates and posterior aspect of the thighs on the perineal tissues through the skin and subcutaneous tissues over the base of the perineal body and fourchette (abundant adipose tissue is, he thinks, a contributor, in primiparæ, at least); and also he believes some amount of resistance to distention of the pelvic outlet is produced by the tension or traction of the stretched *glutei maximi* on the coccyx and posterior surface of the great sacro-sciatic ligaments. In this acquired tension the powers of parturition, or the obstetrician's arm, or both, find an additional element to be overcome, which is also met by the presenting part a little nearer the perpendicular, so that increased power is demanded,

and the force not only overcomes the resistance, but does so by more or less solution of the continuity of the resisting body,—the vulvo-perineal tissues. Whereas in the straight attitude the natural obtuseness of the angle of inclination of the perineal plane is preserved, and whatever laxity of parts is present is not interfered with,—thus by diminished resistance expediting labor and helping to maintain the integrity of the pelvic floor.

As a practical evidence in favor of his method he cites his results regarding perineal laceration, mentioning for comparison the proportion of cases of this mishap given in the standard works, Schroeder describing some degree of laceration as occurring in sixty-one per cent. of the cases, while Dr. Duncan's deputies at the Edinburgh Maternity experienced in the most favorable view fifty-two per cent. of perineal lacerations in twenty-five cases of unaided primiparous labors. Considering slight posterior tears of less than one half an inch to belong to the fourchette, in that series of twenty-five cases were thirteen instances of laceration of the perineal body, four of the fourchette, and eight in which none of the so-called "inevitable" (lacerations) took place. The author cites (hardly fairly, as it seems to us), as further examples of what the flexed position alone can accomplish, two cases of primiparæ coming under his own observation, but where he was not present when the child was born. One had assumed the dorsal decubitus, with the knees well drawn up; the other was delivered at stool. They were cases of head presentation at full time. The first child was of average size, the second over average, and both perinaeums were ruptured to the external sphincter ani. Obviously the position might be described as being curved in both instances, though it might be doubted if the rupture could be laid solely to the position, as the labor was presumably rapid.

In favor of his "straight" position Dr. Macdonald says: "What have I to tell of the straight-bodied lateral position? Firstly, I rely upon the general statement of nearly sixteen months' experience of its beneficial results; and, secondly, I adduce special evidence derived from twenty-five primiparous cases, in which this position was used, as well as mention corroborative cases. Time will not permit of much detail, but, briefly, eleven out of the twenty-five were head presentation forceps cases, and in four there was no laceration, or only the 'inevitable'; in four the fourchette was more or less lacerated; and in three the perineal body was in various degrees trenched upon (from slightly to within a quarter of an inch of the anus in a case of rigidity). Fourteen were unaided deliveries, and in ten the fourchette was entire, in three it was lacerated, and in one the perinaeum was half torn by both shoulders shooting down together. They were full-time occipito-anterior presentations save one."

The weights of the children are given to show that they were of at least average size, and the author says that with this method, including aided and unaided cases, "we find a record of only sixteen per cent. of laceration of the perineal body, which, even in view of the very favorable figure, through care being taken, of Olshausen quoted by West (twenty-one per cent. in primiparæ), goes to prove a considerable balance of practical influence to be accorded to an attitude whose benefit we theoretically at first glance perceive. Corroboratively, and as leading up to an universal affirmative proposition, I may mention in multiparæ an oc-

cipito-posterior, face becoming occipito-posterior, an occipito-posterior forceps case, a breech, and a case of podalic version, all delivered in the straight-bodied position without laceration.

As to the *method*: In unaided cases it is simply to place the patient longitudinally in bed to commence with (unless an extraordinary vaginal examination be requisite), and then to straighten the limbs as the presenting part descends upon the perinaeum. In forceps deliveries the patient's shoulders are brought round by the nurse parallel to the edge of the bed, while the operator holds tight his grasp; a little additional assistance places the patient further from the edge, but within convenient reach, a procedure in which there may be theoretical but no practical difficulty."

BROMIDE OF ARSENIC IN DIABETES MELLITUS.

Soon after the announcement by Dr. Clemens of the benefit to be derived from bromide of arsenic in diabetes the remedy was employed in this disease by Professor Korányi, in Budapest. The medicine was administered to a man twenty-two years old, who when entering the hospital was so weak that he could with difficulty ascend the steps to the clinic at the time of his admission, February 15, 1882. Through the administration of the bromide of arsenic this patient was so greatly benefited that on May 9th he was discharged from the hospital, and was at once enrolled for military duty. During the time of treatment his weight increased from 48.5 kilogrammes to 56.6 kilogrammes, and the loss of sugar in the urine, which in the first few days varied in amount from 170 to 411 grammes in twenty-four hours, was entirely suspended. This surprising result continued after the patient was given a mixed amylaceous diet, and the arsenic was withheld. Before the arsenic was prescribed at all, the patient was for some days confined to a strict diet, by which means the amount of sugar was sensibly diminished from 298 grammes by mixed diet to 113.52 grammes in twenty-four hours. The diet consisted of breakfast of bitter Russian tea, two to three soft-cooked eggs, or bacon; dinner, soup, cooked beef, roast meats, with green vegetables. During the whole day one water biscuit (wassersmell). The first cycle of treatment with bromide of arsenic and animal food lasted eleven days, in which the dose of the drug was increased from three to six drops. The result must be acknowledged a most brilliant one, for on the eleventh day (21st March) sugar could hardly be detected in the urine, and steadily diminished day by day. During the treatment the average amount of sugar excreted was 55.35 grammes per twenty-four hours, that is, half the amount which was previously lost during the time in which the patient was treated by means of an animal diet, or one fifth the original quantity lost daily by the patient. The diet of animal food was now resumed without the medicine, when traces of sugar could be detected in the urine at times, while at other times none could be detected. On the sixth day the patient was given rice in addition to his previous diet, when sugar appeared to the amount of one per cent. in the urine, and the treatment by the arsenical bromide was at once resumed. From this time the medicine was continued in the dose of five drops daily for twenty-seven days, with a modified diet,

containing, in addition to meat, 150 grammes rice and two biscuits daily. During this period sugar was almost always absent from the urine, never being found in a greater amount than 0.1 to 0.3 per cent. After this for a period of some days, the diet was made to include a variety of amylaceous substances, and the medicine entirely withheld, and the only variation was that on two days sugar appeared to the extent of twenty-four and twenty-nine grammes, respectively, in the urine. During the remainder of the time the urine was absolutely free from sugar.¹

[The translator has employed the same remedy as is here mentioned, a compound of bromine with arsenious acid, the nature of which is not yet satisfactorily determined, in the treatment of a case of diabetes mellitus of long standing, in which there has been a loss of thirty-three per cent. of the original weight, ravenous appetite, tormenting thirst, and an excretion of urine amounting to many quarts daily. The amount of sugar in the urine amounted to 35.71 grammes per fluid ounce, or seven and one seventh per cent. The result of treatment by means of this new remedy is awaited with much interest. — A. N. B.]

CHRONIC STARVATION AND "DELICATE" FEMALES.

DR. GRAILY HEWITT, in the opening address before the Section of Obstetric Medicine, at the recent meeting of the British Medical Association, spoke of what had been in his experience a fruitful cause of that train of symptoms often called *delicacy* in young females, and usually associated with some displacement or other abnormality of the generative system. He says:—

"Physiology teaches the necessity for a continuous supply of a certain quantity of food. The popular impression is that some people do not require so much food as others; and, consequently, important quantitative diminution in the supply often escapes attention. I must confess that, not very many years ago, I shared in the popular impression. What induced me to form the opposite conclusion was that, in the first place, I was struck with the fact that in almost every case coming under my notice a state of what was termed 'weakness' by the patient had been notably present; and, secondly, that, on inquiry, this weakness was almost always found to be associated with a notably deficient dietary. For the last six or seven years I have tested the accuracy and applicability of these generalizations, by carefully inquiring into the past history of patients, mostly suffering from some uterine or ovarian disease, or some affection incidental to childbed, and these conclusions have stood the test of this long-extended inquiry. I have to state the important conclusion that a continuous insufficiency of food, or what may be termed a 'chronic starvation,' more or less intense in different cases, was found to have existed almost universally. Consequently, I have naturally been led to consider chronic starvation as a most important factor in disease, certainly in those classes of cases which have come more particularly under my notice."

After giving a few illustrative cases he continues:—

"I have been much interested in observing, also, the effects of previous insufficiency of food in appar-

ently predisposing patients to attacks of puerperal septicæmia. In the cases of this disease which I have seen in consultation, I hardly recollect having seen a case where the patient so affected had, during the pregnancy, lived fairly well; and the worst cases have been those in which the patients fed badly and insufficiently during the pregnancy, and had been fed on a gruel diet after the labor was over. In cases where severe sickness during the early part of the pregnancy prevents the proper nutrition of the patient, the system is liable to become much impoverished, and an insufficient dietary may be, and often is, the preliminary to a dangerous childbed.

"With very few exceptions, and those exceptions only tending to prove the rule, it is, I hold, impossible to find patients suffering from chronic uterine disease who have not undergone at some former period what may be termed a starvation process; and careful inquiry generally elicits the fact that the quantitative deficiency in the diet extended over a considerable period. In many cases the patients are found to be still under the influence of a deficiency in this direction, and to be 'eating,' as the expression is, 'next to nothing.'

"The period of life during which quantitative deficiencies in the dietary are most common is the two or three years immediately following the arrival of puberty. The girl is at school probably, her appetite is bad, or the food is not palatable, or is deficient in important particulars, or, as I have found in some cases, she eats little in order to keep thin; the strength fails, the appetite diminishes, and a habit of taking little is formed,—particularly little animal food is taken. Three or four years of the most critical stages of life are thus passed,—a time at which the body should be growing fast, and to maintain this growth in adequate vigor large supplies of nutritious material are required, instead of which the supply is far below the normal standard. The result is a general impairment of vigor and of vital action. On the generative organs the effect is, as I have observed in numbers of cases, most decidedly injurious; and the effect in most instances is of this kind, that the tissues of the uterus lose their normal firm, healthy consistence.

"It is generally admitted by authorities on the subject of diet that nitrogen is the most essential of all foods, and that a certain amount—about three hundred grains—should be taken daily. In cases of chronic insufficiency of food, it appears that the diminution in quantity of food most frequently affects the nitrogen. Meat is the article of diet which, as a rule, is the source of the greater part of the needed amount of nitrogen, for in England, at all events, meat is the popular article of food; and, in cases of chronic starvation, we mostly find that the quantity of meat taken is exceedingly small. 'Never a meat eater,' 'do not like meat,' 'have got out of the habit of taking meat,'—such are common replies made to interrogations of patients under these circumstances.

"No doubt meat can be replaced dietetically by other foods containing nitrogen in sufficient quantity; but practically, owing to the habits of families, good substitutes for meat are not easy to find. The weakly one of the family is too often allowed to take her own course, and, if she does not take meat, often gets nothing sufficiently nitrogenous to answer the same purpose. Of all the nitrogenous foods meat is admitted by all authorities to be the most easily digested, most easily assimilable, and most rapid in its nutritive action.

¹ Wiener Med. Zeitung, January 16, 1883.

Milk is, of course, a most valuable alternative food; but in these cases of absence of sufficient meat we do not find it has ever been taken in any such quantity as to make up for the deficiency; and the quantity of bread consumed, even supposing it to be pure and of good quality, is in such cases entirely inadequate to supply the required quantity of nitrogen. I need not allude to the effect of deficiency in the other constituents of the diet. It is sufficient for my present purpose to show that the nitrogenous elements, while they are of all the most important, are those which are markedly absent in the cases now under consideration."

THE TREATMENT OF ATONIC DYSPEPSIA.

IN an article on Atonic Dyspepsia¹ Dr. J. Milner Fothergill thus discourses on the question, What is it which needs improving, the assimilation of hydro-carbons or the assimilation of albuminoids, or both?

"This is a matter too little insisted upon. Too commonly action is taken rather blindly, and malt extract (diastase), or pepsin, or pancreatic preparations prescribed without that discrimination which is so desirable. My own rule, so far as it is formulated, and it needs some corroboration (possibly some correction), is taking the following direction: When the patient is spare and too thin, then starch and sugar are indicated, and diastase should be added to farinaceous matters. Surplus sugar is laid down in the body as fat, that is, within the storing capacity of the organism. Then when there is any tendency to glandular degeneration, and that growth of lowly connective tissue spoken of commonly as tubercle, the indication is some fat which can be assimilated, of which cream, butter, and cod-liver oil are the most digestible forms. When it is desirable to increase the power of assimilating fat, there are several measures which may be adopted, singly or together. There are agents which stimulate the flow of bile, which emulsionizes fat so that the pancreatic secretion may further act upon it, and the most useful of these is ipecacuanha. Either has been found to stimulate the flow from the pancreas, and so aid materially in the assimilation of fat. It might be given with liquor pancreaticus and cod-liver oil. Sometimes when cod-liver oil is not assimilated, it is well to resort to the following plan: The oil is observed unchanged in the stools, *en masse*, never having been divided into an emulsion. Here it is well to remember that a fatty acid helps in the emulsifying of fat. So give some castile soap, say two grains, with two grains of dried ox-gall, in a pill, about two hours after a meal, when the contents of the stomach are passing into the duodenum. The fatty acid and the bile assist the natural efforts, and then the assimilation of fat is often materially aided."

Regarding indications to be gained from the appearance of the tongue, the author remarks:—

"In very acute conditions it may become necessary to give milk and milk gruel already largely digested by the addition of liquor pancreaticus, or these may be given at times with ordinary milk and seltzer water or lime-water at other times in the day. Such are conditions where there is much gastric irritability with vomiting, and a tongue denuded of epithelium or seen to be covered by a growth of young epithelium. This

condition is not uncommon in the course of phthisis, and when it shows itself it requires its own peculiar treatment, all others being abandoned for the time at least. Here the line to be taken is that of alkalies and bismuth with or without some hydrocyanic acid. Whenever the tongue is raw or bare then alkalies are to be given, and acids carefully eschewed. If the reader has doubts about the last, let him just try the experiment with his eyes open, and watch it. It will not be long before the results will be apparent to him. Bismuth with soda in calumba is the old and well-known combination for such state, and with it the milk dietary just described may be combined. More commonly, however, a less grave and acute condition is found where the state of the tongue is just the opposite, namely, covered with a layer of dead epithelium. Here acids are not only unobjectionable, but are very useful. Indeed, soda sulphate with some acid is the combination which gives the most satisfactory results. Under this the tongue soon cleans, the appetite returns, and the stools are of a normal color. When the primæ viæ are once more acting normally and in a healthy state, then, and not till then, may some chalybeate be given. But as long as the liver is in any way disturbed chalybeates are useless, and usually disagree. When the appropriate time comes then iron is useful, but however impatiently the time is awaited it is well to be patient. To resort to iron prematurely is a very common mistake. Sometimes when the tongue is placed in a side light a yellow shade can be detected, and so long as that remains so long must chalybeates be withheld."

Among hepatic stimulants he places more dependence on ipecac than on mercury, arsenic, euonymin, baptisin, iridin, leptandrin, or any other of the so-called cholagogues. Of this he says:—

"A century of experience tells of the utility of ipecacuan in indigestion. It was a constituent of the dinner pill of the last century. Not only does it stimulate the liver, and so be useful in cases of indigestion where there is either bile acids formed in excess or lithates present (that is, the peptones which find their way into the portal vein from the intestinal canal, and which, converted into proteids, are elaborated into the albumen of the liquor sanguinis by the liver normally, are transformed instead into bile acids or urates; the patient loses flesh, and on a flesh dietary only makes more bile or more lithates without gaining weight), but ipecacuan is a "pepsin persuader" from its action on the gastric lining membrane with its multitudinous glands and follicles. Ipecacuan combines properties, indeed, as does no other agent, in my opinion. Then there is often atony, either general or in the bowel, and for this strychnia is an admirable remedy. Perhaps, too, flatulence, for which a carminative is indicated. Then there is the vehicle, which may or may not be a laxative, according to the case. The pill would stand then somewhat as follows:—

R Strychniæ	gr. 1-20.
Pulv. ipecacuan	gr. 2-3.
Pulv. piper. nig.	gr. iss.
Ext. gentian	gr. i."

— Dr. Squibb has substituted for the ordinary blue and red litmus paper a single color, namely, purple. This purple litmus paper turns red with acids, blue with alkalies. It is claimed to be much more delicate and convenient.

¹ Medical Record, September 1st.

MORBID CHANGES OF THE THROAT, LARYNX, AND AIR-PASSAGES IN SOME ACUTE INFECTIOUS DISEASES.

THE *Edinburgh Medical Journal* (July, 1883) quotes from Dr. E. Löri, Budapest (*Jahrb. f. Kinderh.*, xix. 1). In measles, twelve to thirty-six hours before the appearance of the skin rash, there is a diffuse or macular hyperæmia of the mucous membrane of throat, larynx, and air-passages, diffuse usually in the mouth, macular on the tonsils and back of the throat. Within twelve hours from the appearance of this hyperæmia there occur small papules, first on the palato-glossal folds. About the time that the skin eruption appears there is profuse catarrh of pharynx, larynx, and trachea, with rapid shedding of epithelium, and frequent formation of superficial erosions. In the trachea the swelling around these latter may give rise to stenosis. According to the writer the appearance of such ulcers in the larynx augurs the occurrence of tuberculosis. In scarlatina the throat is affected twelve to thirty-six hours before the outbreak of eruption. The writer states that there is often a sudden disappearance of the affection of the mouth and pharynx coincident with the eruption on the skin coming out.

Frequently the eruption in the mouth closely resembles that found with measles. In rubeola there is also hyperæmia, diffuse or spotted, of the larynx and trachea. In small-pox the mouth is affected at the same time as the skin. The pustules are small and imperfectly filled, dry up in two or three days, and in six days are only represented by red spots. Bleeding from them is very common. The writer recommends the use of ice poultices round the neck, ice internally, and such astringents as tannin applied after puncture of the pustules. In chicken-pox there occurs either diffuse hyperæmia of the mucous membrane, or a few scattered pustules. In typhus and typhoid, acute catarrh of the pharynx, larynx, and trachea is of frequent occurrence, and often proceeds in the larynx to the formation of ulcers, which have little tendency to heal, and occasionally, about the sixth or eighth week of the disease, cause perichondritis. For this latter condition, "when diagnosed with certainty," the writer recommends tracheotomy as early as possible. In whooping-cough there is usually some catarrh of the larynx and trachea, and bleeding from the mucous membrane is frequent. The appearance, during the course of whooping-cough, of ulcers in the larynx the writer regards as very suspicious of the onset of phthisis.

REPORTED MORTALITY FOR THE WEEK ENDING SEPTEMBER 8, 1883.

Deaths reported 2773 (no report from Buffalo): under five years of age, 1204: principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhoeal diseases) 826, diarrhoeal diseases 396, consumption 344, diphtheria and croup 139, lung diseases 133, typhoid fever 98, malarial fevers 57, scarlet fever 51, whooping-cough 37, cerebro-spinal meningitis 15, small-pox 12, measles nine, erysipelas six, puerperal fever five, typhus fever one. From *malarial fevers*, New Orleans 17, St. Louis 12, New York 11, Brooklyn nine, Chicago and Baltimore three each, Philadelphia two. From *scarlet fever*, Philadelphia 18, Baltimore seven, Chicago six, Brooklyn and St. Louis five each, New York and Boston two each, District of Columbia, Lowell, Worcester, Springfield, Waltham, and Woburn one each. From *whooping-cough*, New York eight, Brooklyn and District of Columbia six each, Chicago five, Philadelphia, New Orleans, and Pittsburgh three each, Boston two, Fitchburg one. From *cerebro-spinal meningitis*, New York four, Philadelphia two, Baltimore, Cincinnati, Providence, Lawrence, Lynn, Springfield, Salem, Holyoke, and Fitchburg one each. From *small-pox*, New Orleans eight, Philadelphia four. From *measles*, New York four, Philadelphia and Baltimore two each, St. Louis one. From *erysipelas*, Philadelphia four, Brooklyn and Baltimore one each. From *puerperal fever*, St. Louis two, Philadelphia, Chicago, and Somerville one each. From *typhus fever*, New York one.

Twelve cases of small-pox were reported in St. Louis; typhoid fever 56, diphtheria 18, scarlet fever 13, and measles one in Boston; scarlet fever nine, and diphtheria seven in Milwaukee.

In 36 cities and towns of Massachusetts, with an estimated population of 1,134,834 (estimated population of the State

1,922,530), the total death-rate for the week was 21.21 against 22.96 and 25.57 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending August 25th the death-rate was 19.1. Deaths reported 3149: diarrhoeal diseases 273, acute diseases of the respiratory organs 160, scarlet fever 115, measles 88, fever 59, whooping-cough 44, diphtheria 30, small-pox (Birmingham six, Liverpool two, London one) nine. The death-rates ranged from 12.9 in Huddersfield to 30.2 in Preston; Bradford 13.2; Birkenhead 15.3; Leicester 16.5; London 17.9; Nottingham 19.9; Birmingham 21.5; Leeds 21.7; Liverpool 23; Manchester 23.4; Newcastle-on-Tyne 27.6. In Edinburgh 15.7; Glasgow 25; Dublin 21.2.

For the week ending August 18th, in 167 German cities and towns, with an estimated population of 8,475,284, the death-rate was 24.7. Deaths reported 4029; under five years of age, 2219; consumption 485, lung diseases 374, diarrhoeal diseases 351, diphtheria and croup 155, scarlet fever 67, typhoid fever 65, whooping-cough 61, measles and röteln 58, puerperal fever 16, small-pox (Heilbronn two, Bamberg one) three. The death-rates ranged from 13 in Karlsruhe to 38.6 in Munich; Königsberg 27; Breslau 34.5; Dresden 25.2; Berlin 27; Leipzig 23; Hamburg 22.1; Cologne 22.4; Frankfurt a. M. 19.6; Strasburg —.

For the week ending August 25th, in the Swiss towns, there were 25 deaths from diarrhoeal diseases, consumption 14, lung diseases 12, measles four, diphtheria and croup three, whooping-cough one, typhoid fever one. The death-rates were at Geneva 16.4, Zurich 16, Basle 11.1; Berne 16.9.

The meteorological record for the week ending September 8th, in Boston, was as follows, according to observations furnished by Sergt. O. B. Cole, of the United States Signal Corps:—

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.	
		Daily Mean.	Daily Maximum.	Daily Minimum.	7.23 A. M.	3.23 P. M.	11.23 P. M.	Daily Mean.	7.23 A. M.	3.23 P. M.	11.23 P. M.	7.23 A. M.	3.23 P. M.	11.23 P. M.	7.23 A. M.	3.23 P. M.	11.23 P. M.	Duration. Hrs. & Min.	Amount in inches.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM SEPTEMBER 7, 1883, TO SEPTEMBER 14, 1883.

BANISTER, J. M., first lieutenant and assistant surgeon. Assigned to duty at Fort Adams, R. I. Paragraph 3, S. O. 170, Department of the East, September 10, 1883.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING WEEK ENDING SEPTEMBER 15, 1883.

BEARDSLEY, G. S., surgeon, and LIPPINCOTT, GEORGE C., passed assistant surgeon, detached from the Galena and placed on waiting orders.

PERCY, H. T., passed assistant surgeon, detached from the Naval Hospital, Norfolk, Va., and ordered to the U. S. S. Galena.

BRIGHT, GEORGE A., surgeon, detached from Naval Rendezvous at Philadelphia, Penn., on September 30th, and ordered to the Galena October 1st.

URQUHART, R. A., passed assistant surgeon, ordered to the Alert on October 6th, and on the arrival of that vessel at Yoko-

hama, Japan, to be detached, and to report for duty at the Naval Hospital at that place.

SIMONS, M. H., passed assistant surgeon, to be detached from the Naval Hospital, Yokohama, Japan, on the reporting of his relief, and ordered to the U. S. S. Alert.

AMERICAN ACADEMY OF MEDICINE. — The annual meeting of the Academy will be held at the New York Academy of Medicine, 12 West Thirty-First Street, New York, on Tuesday, October 9 (three o'clock P. M.), and Wednesday, October 10, 1883.

RICHARD J. DUNGLISON, Secretary.

BOOKS AND PAMPHLETS RECEIVED. — A Practical Treatise on the Medical and Surgical Uses of Electricity. Including Localized and General Faradization, Localized and Central Galvanization, Franklinization, Electrolysis, and Galvano-Cautery. By George M. Beard, A. M., M. D., and A. D. Rockwell, A. M., M. D. Fourth Edition. Revised by A. D. Rockwell, M. D. With nearly Two Hundred Illustrations. New York: William Wood & Co. 1883.

A Text-Book of General Pathological Anatomy and Pathogenesis. By Ernst Ziegler. Translated and Edited for English Students by Donald MacAlister, M. A., M. B. New York: William Wood & Co. 1883.

CHANGES IN THE SYSTEM OF MEDICAL EDUCATION.¹

BY E. N. WHITTIER, M. D.,

Instructor in the Theory and Practice of Physic in the Harvard Medical School.

I DEEM it a rare privilege, Mr. President and Fellows of the Society, to be permitted to ask your attention to changes of great importance, already effected, or in process of adjustment, in the system of medical education.

I shall attain the high object I have in view, if I shall present clearly and concisely the defects of the old, the advantages of the new, and some of the causes contributing to the modifications noticeable in the scheme adopted by the most progressive of our modern schools.

It is not needful for the purposes of this paper that I should seek outside the limits of this Commonwealth material for illustration. In all that pertains to education, academic, technologic, collegiate, in law, in divinity, or in medicine, the Massachusetts standard is the highest.

The defects of the earlier schemes were most conspicuous in the lack of method in imparting instruction, in the absence of any effort well sustained and continuous through the whole time given to medical pupilage, and, in the control exerted over the students, by interests conflicting with medical education, during the months intervening and between the winter sessions; work preparatory for the lectures was in most instances wholly neglected or poorly directed; the embryo physician cast off at the end of the fourth month of intra-medical life, sought the farm, the work-shop, or the bench, or "plodded his weary way" through the mazes of anatomy, physiology, and chemistry in "regions remote, unfriendly, solitary, slow," or he again became the pupil of a physician already overtaken by business, and by that reason, even if generously qualified, but little inclined to act as preceptor.

It was a sign full of promise, where three years' study and attendance on two winter courses were prerequisites to an examination for the degree of doctor in medicine. Possession of two sets of tickets was deemed good and sufficient evidence of the one and the certificate of a physician in good standing of the other of these primary qualifications for a degree.

I need not remind you of the various methods adopted to evade these preliminary requirements; of the herding of classes, of professorial ambition better gratified by proceeds than by products, or by quantity rather than by quality of attendance; of the dread array of examiners, when ten minutes to each chair was an ordeal better qualified to evoke evidence of fullness from the presence of an as yet undigested mass of medical facts than to determine what was likely to be retained, digested, and absorbed.

¹ Read before the Massachusetts Medical Society, at its Annual Meeting, June, 1883. The following note is published at the request of the writer of the paper.

MASSACHUSETTS MEDICAL SOCIETY.

ROXBURY, July 7, 1883.

MY DEAR DOCTOR, — Your paper, read before the Society at its recent meeting, was, in accordance with custom, referred to experts.

The subject of the paper not being of the nature of those usually published by the Society, I regret to inform you that their verdict was not favorable for its publication. I herewith return the paper to you.

Very truly yours,

F. W. Goss, Recording Secretary.

DR. E. N. WHITTIER.

Under such conditions degrees must have been given more for what men were believed to be capable of acquiring, rather than for what they could have already acquired.

For instance, one of the most distinguished surgeons of modern times, whose name was a household word in this community two generations ago, had, to my knowledge among many others, as a pupil for three long years, one of whom he asked no questions, for whose advancement he made no effort to impart instruction. In a neighboring city I entered the office of a physician famed for his acquirements, widely known for his skill, of great ability, and possessed of a large and exacting practice. I left at the end of the first half year. I had been asked no questions, I had been given no instruction. I had my certificate and little else. Facts such as these, old to the oldest, but new to the youngest here present, controlled the educational efforts of fifty, thirty, and even twenty years ago.

The strongest influences antagonizing the system of medical pupilage as it formerly existed were the very defects alluded to. The founders of the Tremont Medical School determined upon a course of study in large degree supplementary to, but in a larger and more important sense essentially a part of, the winter session. Individual medical instruction became almost an impossibility, for the best medical talent of the community arrayed itself at once by the side of coöperative medical education, the custom of medical apprenticeship was quickly and practically ended, and the gracious influences continued to increase, in power and effect, forcing by their own intrinsic merit the union of the summer and winter sessions, the blending of conflicting interests into harmonious and well-directed efforts continuous throughout the academic year, and perfected a scheme "to carry the student progressively and systematically from one subject to another in a just and natural order." The advantages of the continuous course in the newer system of medical instruction, have fully justified the sound judgment of the promoters of the scheme.

Broken, disjointed, and fragmentary efforts must of necessity give but imperfect results. The study of the various branches of medicine, entered upon with a high appreciation of the value of a systematized and carefully planned scheme, whose various elements are judiciously and logically arranged, must needs be followed by the highest attainment, and the best preparation for an honorable and useful career.

Division into classes, rigid scrutiny of individual members, restriction to the work assigned to the class for the year, and examinations conducted with the utmost fairness, and adjusted in accordance with the experience of the examiner to the capacity of men of average intelligence, are the salient features of the plan now adopted.

The value of the habits of study, and of the mental discipline acquired by men of collegiate education, is nowhere seen to greater advantage than in the classes composing the medical school of to-day; and the relative increase in the number of men who, by their scholarly habits, easily reach the highest grade as medical students is particularly noticed in the matter of hospital appointments, into which of necessity to a considerable degree scholarship now enters. The present difficulty is not to find a sufficient number of good men well prepared, but to select out of the very large

number of desirable men those best qualified for these honorable positions.

Competition, which in medicine now begins with its study, and in the matter of these appointments is sharp from the outset, is thus felt through the whole of a medical student's life, and the immediate goal of his ambition, a hospital appointment, is with good reason believed to be dependent in large measure upon good work in the school. The rapid growth of our hospitals, calling for corresponding increase in the number of undergraduate appointments, offers advantages of the largest practical value to the students. The lengthening of the term of service in the Boston City and Massachusetts General Hospitals to eighteen months, considered with reference to the class of men appointed, may impair in no small degree the success of the fourth year course, so long as it remains optional; for the hospitals must always be regarded as dangerous competitors for the time of the very desirable grade of students able and wishing to extend their studies beyond the three years now prescribed, and hospital experience will always be found in the opinion of undergraduates to outweigh the advantages of the instruction in the special and general subjects assigned to the fourth year. But at the present time no convincing argument can be offered for a more intimate relation between the school and the hospitals. Practically, and through the courtesy of the hospital management, all the material desirable for instruction while in the control of the hospital authorities is freely at the disposal of the Board of Instruction. It is not from lack of material, nor through any obstacles created by hospital authorities, that a large percentage of the cases in indoor and out-door service fails to be of value for the purposes of medical instruction. Nor can it be said that the subjects themselves are unwilling. The more intelligent, and because of their greater intelligence the more desirable patients, are the quickest to appreciate and to avail themselves of the great personal advantages arising from the most critical analyses of their various diseases. At no time are such examinations carried to a greater degree of excellence than during the hours devoted to clinical instruction. The supply of material for all branches of practical surgery and medicine, and for most of the special branches, is in excess of the demand, and is increasing rather than diminishing; and through the intelligent and cordial efforts of the able executive officer of the Massachusetts General Hospital, Dr. Whittemore, a new out-patient building has been so planned as to quadruple the conveniences and opportunities of the old, and to place clinical advantages of the most desirable character more directly than ever before, essentially at the disposal of the school.

An important question bearing upon the relative value of the instruction given by hospital physicians and surgeons here suggests itself.

It is not true that the men having control of the largest amount of clinical material are, by reason of this or any other single fact, the best teachers, nor can it be said that the best teachers are constantly so situated that they can control and select cases such as shall be suitable for illustration of the subjects they desire to demonstrate, and the defect bids fair to be perpetuated; for there are no indications of a change from the present system of a few months on duty and many months off to what is known as the continuous service.

It will be a fortunate day for the cause of medical

instruction when the gentlemen prominently connected with the clinical departments of the school shall have an opportunity to follow, in a regular and systematic manner, the didactic exercises, or when, in harmony with a properly controlled and previously arranged plan, cases can be presented which shall demonstrate clinically the important facts illustrated in the lectures, and at the same time reinforced by text-book instruction.

Yet the advantages are not wholly on the side of the new system, for while the tendency of the present day is strong in the direction of conscious, systematized, and selected knowledge, it leads the student too far from the realm of practical knowledge and applied power. It may with some show of reason be claimed that the error is not in the scheme so much as it is in the limitations placed upon its development by the short time given it by the student. Yet it is true that "the ancient and serious diligence of Sydenham," by which he achieved so much, his master principle in practice and in thought, has given place to the study of essence and of cause, of structure more than of function, of the varying phenomena rather than of the natural progress of disease, and thus the need of cultivating the powers of observation and the art of medicine is lost sight of in the desire to impart the largest possible knowledge of the science of medicine.

The older system permitted the more immediate, the newer system adopts the mediate, cognizance of disease, and is inclined to reject as of too little value the governing principle of the old, that it is by their own eyes, and their own ears, and their own minds that students must observe, and learn, and profit.

In his grateful tribute to the memory of his old master, Dr. Holyoke, whose name appears as the first among the incorporators of this Society, Dr. James Jackson wrote, "After a time he allowed me to walk with him, and to see his patients." Dr. Latham checked his pupils on the threshold of St. Bartholomew's, saying, "In entering this place, even this vast hospital, where there is many a significant, many a wonderful thing, you shall take me along with you, and I shall be your guide."

The strength of the old method was in this intimate relation between master and pupil, and any violation of this governing principle in medical instruction will impair the power of the new system. But there will be found on careful inspection a marvelous increase in the facilities afforded students in that they are placed as never before in direct immediate contact with cases assigned them for their instruction, and while the master and pupil may not now as formerly walk side by side, in a better and more important sense they walk hand in hand in their allotted and chosen studies.

From a somewhat extended opportunity for observing the influences exerted and the results attained by the systems adopted for the instruction of medical students, I may lay claim to the privilege of presenting and of discussing some of the features of the more advanced methods.

The aim of the best school is not to graduate large classes fairly fitted for the active duties of professional life, but classes, whether they be large or small, eminently qualified for the practice of the art of medicine, and in the present advanced and rapidly advancing condition of the knowledge which it is useful to impart to undergraduates, two methods of solving the vexed question, how to compress the needed knowl-

edge into the short time to be allotted to its acquirement, present themselves. One plan, as yet *sub judice*, extending the time to four years, and another, the discussion of which has already begun, is to include in the preliminaries such knowledge of anatomy, chemistry, and physiology that men shall be fitted for immediate practical work in the laboratory and at the dissecting table. In this way didactic exercises and text-book instruction could in great part be finished during the second year, and the third-year students, having already acquired the requisite knowledge of theoretical and scientific branches needful for the purpose, could be assigned exercises, and be frequently examined on subjects more intimately associated with the art and practice of medicine; for though in all that pertains to the science of medicine graduates of to-day are wonderfully proficient, yet it is evident that under the present crowded condition of the third year, and from the scanty time allotted to clinical exercises, limitations are placed upon the best results, and these limitations are so great that comparatively few undergraduates have acquired adequate knowledge of the art of observation, or have been sufficiently drilled in the application to the practice of medicine, of its science and theory.

In clinical exercises the student has his only opportunity of proving, and the professor his best method of testing, the theoretical and practical value of the instruction imparted. Unfortunately for the best interests of the students these exercises are associated with so much that should precede, and, in the latter part of the year, with the pernicious process of "cramming" for the final examinations, that great difficulty is experienced in getting the men most needing clinical instruction sufficiently well to the front so that they are brought immediately under the supervision of the instructor. This difficulty is, however, likely to be removed by the rapidly increasing tendency to divide and subdivide the class into sections, and to thus bring individual students more directly and more frequently in contact with patient and instructor.

The effect of close proximity, quick questioning, and ready response, the breaking down of barriers thrown up in class work, and the substitution for these hindrances of many familiar aids, the influence which a judicious instructor can exert in the direction of implied coöperation and interdependence, the exercise of the power which lifts the work of the hour up to the level of the student's ideal, and carries straight home to his heart and understanding a vivid, realizing sense of the importance of his work, these are a few of the many advantages which division into sections has over the old method of class exercise for the detail or for the routine of clinical instruction.

It is not sufficient for the best results of a clinical exercise that it should rest with the announcement of the diagnosis, and yet it too frequently happens, from a defective application of the rules for conducting the exercise, from the limitations placed upon the time to be given the case, or from other and not easily controlled conditions, that but little or no time is given to the consideration of the other and very important element, the treatment, "for the observation which does not teach the art of healing is not that of a physician, it is that of a naturalist," and one of the strongest claims to the success attained by the new system should be that it teaches men more and better things of the art of healing.

Again, if it be that students are better prepared than formerly by their more extended preliminary education to grasp and comprehend both the difference and agreement in symptoms, the instructor ought to work in a manner not possible under the older system, for devices not applicable formerly, from lack of suitable material or from the want of the present conveniences, can now be constantly employed.

Among these devices none deserves higher rank than the use of the blackboard, and no clinical exercise can be held to be complete in which this important aid is unemployed, for by this the instructor appeals to both the sight and hearing of his class, and places plainly before them in such way that it need not escape the observation of the most superficial the various stages and steps of the mental process pursued by accomplished clinicians in their passage through the labyrinth of rational and physical signs out into the region of diagnosis and treatment. For instance, the use of the blackboard enables the instructor to so collect and display the rational and physical signs that no material fact can escape or be forgotten, to so present the arrangement or grouping of symptoms that the points of agreement or difference can be more readily seen, to adopt the systematic and logical placing of symptoms by employing the device of juxtaposition ("for orderly juxtaposition is requisite in matters of complexity") so that both agreement and difference in the value of signs are made plainer, and to sum up the case by the constant, undistracted iteration and reiteration of the points of agreement.

For instance, the history of a case when written on the black-board should present the signs or symptoms in the order in which they were given by the patient, and whether this order be systematically, chronologically, or logically correct or not, it should be written down as given.

Then the various signs should be rewritten or renumbered, so that the points of agreement or difference can be more plainly seen, and at the same time so grouped that those signs which by proximity impart value to each other and strengthen the group, as suggestive of some disease or of kindred diseases, are placed (by employing the device of juxtaposition) side by side.

The final stage is entered upon, in the effort made by the instructor to increase the diagnostic value of the group of signs, by iteration and reiteration of the points of agreement undistracted by any allusion to the points of difference.

And I believe that these are the most prominent and promising of the methods now employed to impart requisite knowledge of the value, when applied to individual cases, of the great general truths of the art of medicine.

It is not profitable in the limited time assigned this paper to present more than a brief sketch or to touch upon more than one of the various branches of medical education in which marked advances have been made.

The illustration which I shall employ may serve to show that the proper study of the art of medicine includes that of the art of observation, and that the greater worth of the new system resides in the fact that by this method, better than in any other way, students are taught how they can best employ the knowledge they possess; that it gives them safe rules for the analysis of cases, so that at the time, for the time, and in the time at their disposal they can give an immediate value

to the efforts they may make for the relief of their patients; that it teaches men the great advantage of systematized thought, and enables them to apply to diagnosis and treatment a method which shall add to their equipment yet another thoroughly tested instrument of precision. The intent of the system is that the early part of the year is to be employed by the instructor in teaching his class, by his examinations of patients, the rules they should adopt in their examinations, and in the remaining part of the year the exercises are to be conducted by the students under the supervision of the instructor, who holds the student closely to the use of the rules which long experience and many trials have proved to be best calculated to apply to his theoretical and scientific knowledge the most satisfactory test of its real worth.

Briefly stated the method is this: The rational signs, including heredity, age, sex, occupation, mode of living, hygienic influences, locality, previous illnesses, history of present illness, and all that may be learned by questioning (and in this the art of a skilled examiner is plainly set forth), are written on the blackboard, in the presence of the class, and, if need be, carefully rearranged or numbered according to the relative importance of the signs; then the diseases, of which these rational signs are suggestive, are placed in such order, or so grouped, that they are given position in the order of their values. The same course is followed with the physical signs, and, last of all, the conjoint use of rational and physical signs is employed for the purposes of elimination, diagnosis, and treatment.

It has been my very good fortune for a number of years to be so placed that I could follow a considerable number of the exercises in clinical medicine under Professor Ellis, and since his deplored illness many of the exercises in this department of instruction under Professor Minot.

The illustration which I have already alluded to, and have placed on the screen, is wholly, in all its particulars and details of arrangement, a transcript from the note-book of a third year student, his copy of an exercise conducted and written on the black-board in the presence of the class by one of his classmates.

Let us for a moment consider the circumstances under which this exercise was begun.

A woman brought her child to the Out-Patient Department of the Massachusetts General Hospital seeking relief. She was taken into the amphitheatre, where the third class had already assembled, and one of their number was called down from the seats and told that the case was his to examine, governing himself by rules with which he was believed to be familiar. The defective intelligence of the mother and the extreme youth of the child offered many obstacles to securing a satisfactory history of the case. But upon these meagre facts, gained only after much and careful questioning, he based his work. How well he did it is best shown by the fact that one of his classmates, intelligent and observing, obtained for his note-book, and possibly for future use, this outline of the case, and I place it before you just as it was handed to me:—

MEDICAL CLINIC, FEBRUARY 21, 1883.

History. { Girl, age six years. Family history good; previous history good; five weeks ago noticed cough, with pain in left arm (?) and region of stomach; feverish; scanty-muco-purulent expectoration; violent action of heart; loss of flesh and color; appetite poor; no diarrhoea; no vomiting; no evidence of shortness of breath (?); was in bed two weeks; no constipation; does not sleep well; urine negative.

RATIONAL SIGNS.

Cough.	} Acute.	Thoracic.	{ (1.) Pulmonary. (2.) Cardiac. (3.) Pleural.
Pain in left side.			
Muco-purulent expectoration.			
Violent action of heart.			
Fever.			
Epigastric pulsation.			
(1.) Pulmonary.	{ Catarrhal pneumonia. Croupous pneumonia. Capillary bronchitis. Bronchitis.	{ General. Circumscribed.	
(2.) Cardiac.	{ Congenital. Eliminated by history. Acquired. { Endocarditis. Myocarditis. Pericarditis. { With effusion. Without effusion.		
(3.) Pleural.	{ Acute pleuritis. { With effusion. Empyema. { Without effusion.		

PHYSICAL EXAMINATION. (SIGNS.)

Inspection.	Pallor.	{ Right side larger than left. Left side deficient in motion and contracted. Intercostal spaces on left side not seen.
	Emaciation.	
{ Of back.	Lack of symmetry.	{ Congenital pleurisy of left side. Old pleurisy of right side.
{ Of front.	Contraction of left side not so marked.	{
	Pulsation at right nipple { R. auricle. R. ventricle.	
Lateral curvature to right side.	{ If dependent on pleurisy curvature would probably have been towards left side.	
Palpation.	{ Vocal fremitus absent on left side. Apex beat felt in fourth intercostal space near right nipple.	
Percussion (back).	Left side flat.	
Auscultation (back).	Left. Respiration absent at base. Broncho-vesicular at top.	{ Broncho-vesicular throughout.
	Right.	
Diagnosis.	{ Fluid in left pleural cavity; and because of the tendency to purulent effusions in children, and the delicate condition of the child in question, probably purulent or sero-purulent rather than a serous effusion.	

The occasion was one of many opportunities seized by the instructor to test the quality and the quantity of the knowledge of clinical medicine possessed by the student, and to determine whether or not that knowledge was so classified and catalogued that it was available for the purposes of, and in the time allotted to, this exercise, and although it may seem to some that a better plan could have been adopted for the proving of this paper (for the demonstration is defective in many important particulars), and that I should have procured for you an example elaborated, worked out in detail, and finished in all its parts by an instructor, I have chosen rather to rest my case upon the unimpeachable testimony of the instructed; to place before you the work of the pupil, in which, nevertheless, without doubt and without difficulty, you may trace the hand of the professor, and because I am no longer dealing with the means by which this result has been obtained, but with the result itself.

I have the honor to submit, for your inspection and criticism, this work of a third year student, with a high appreciation of the favorable judgment which awaits it, for it is a competent and willing though not too swift witness of an advance in the system of imparting medical knowledge through recent changes in the methods of medical instruction.

— A correspondent writing to a contemporary makes the astonishing statement that he was told by an older practitioner that it was always the latter's habit to destroy monstrosities. The correspondent having had in his practice two acephalous monsters writes to know what his moral and "ethical" duties are in the premises.

THREE OBSTETRICAL CASES COMPLICATED I. BY ALBUMINURIA; II. BY ERYSIPELAS; III. BY ECLAMPSIA AND SEPTICÆMIA.¹

BY C. M. JONES, M. D.

AMONG the perils which beset the lying-in woman eclampsia and septicæmia are probably the gravest. The symptoms which point to these complications are the source of the greatest anxiety to the physician, and no study of them can be too careful. I purpose, therefore, to group together to-night three widely different obstetric cases, not for their rarity, but because they will serve to bring out points of prognosis and treatment which, in my judgment, are sometimes too little considered. The first two will illustrate how the apprehension of these two complications may be dissipated by the course of events, while in the third the life of the patient was twice jeopardized by the successive appearance of each.

CASE I. Albuminuria. January 8, 1879. Mrs. U., primipara, age eighteen, short and stout. History of general good health till about three weeks ago, when she noticed swelling of the feet, which has continued to increase up to date. The legs are enormously distended, so that she can scarcely bend the knees, and the abdomen is in a corresponding condition. Face somewhat puffy. Has suffered much of late from nausea and frontal headache, and the urine has been scanty. She has, however, kept on her feet up to the last moment. Labor pains began at two o'clock P. M., and I first saw her at eight P. M., and found the condition as above described. The bowels had been moved during the day with oil. The head was presenting O. L. A., and the os was soft, dilatable, already the size of a quarter; pains not severe or frequent. A little urine was secured, and examination showed specific gravity 1010, albumen one and one half per cent., hyaline and granular casts. There seemed to me at the time no sufficient reason for active interference, and the case was left in charge of a medical student, Mr., now Dr., Comey, who did not call me until morning. The progress had been slow without any unusual symptoms. The os had been for some time fully dilated, but the head was not advancing. I therefore ruptured the membranes at nine o'clock A. M., January 4th, and a female child was born at 11.30 A. M. The placenta was delivered fifteen minutes later, the uterus contracted well, and there was no untoward symptom. The night after delivery she began to pass water freely. There were 2650 cc. in twenty-four hours, having the same characteristics as before. The free diuresis continued for a fortnight, sometimes reaching 3000 cc. in a day. The albumen and casts gradually diminished. She also had considerable diarrhœa. The cedema diminished with surprising rapidity, and at the end of the fortnight had entirely disappeared.

February 1st. Was able to do her housework.

February 7th. Urine, specific gravity 1013; albumen, a trace; urea normal; very few granular casts.

February 16th. Six weeks after delivery. Urine, specific gravity 1013; albumen absent; slight sediment; no casts; small amount of pus.

This patient had absolutely no medicinal treatment until she began tr. mur. fer. two weeks after delivery. I purposed to give her diuretics, but, fortunately, took

the precaution first to measure the urine of twenty-four hours. Otherwise the medicine would have received the credit which belonged to nature alone.

Albuminuria in pregnant women is not infrequent, but it is exceptional to find so extensive cedema as was seen in this patient. All the ante-partum symptoms, the cedema of feet and face, the nausea, the headache, and the scanty urine, were such as to give rise to the liveliest apprehension of convulsions. I have known forcible delivery to be recommended and carried out with less of reason than here existed, and that, too, in a multipara, where the probability of convulsions is by no means as great as in a primipara. Had such a procedure been undertaken in this case the good result would have been proclaimed as sufficient justification. But such a result following a masterly inactivity, which to be sure is lacking in brilliant effect, makes enormous the responsibility of inducing premature labor in similar cases, and especially so when the viability of the child is not fully assured, for this result is not exceptional. A large proportion of cases of albuminuria when let alone escape the apprehended danger, and if this were otherwise we are not sure of exemption even after operation. In a very considerable number of cases in which convulsions occur they continue or first develop themselves after the uterus is emptied. For these reasons, therefore, the policy which in a vigorous patient leads to active interference on account of the mere apprehension of possible complications seems to me of doubtful propriety.

CASE II. Facial erysipelas beginning on the day of confinement. December 20, 1882, I was called to see Mrs. M., primipara, age twenty-one, who was now eight months pregnant. Health had been good till two days before, when, after exposure, she began to complain of her throat. She had had a chill, was now very feverish; respiration 120, rather weak; temperature 102° F. There was severe inflammation of the throat and tonsils, and on the latter were scattered patches of ulceration. Tongue had a heavy brown coat. There was nothing to indicate that labor was impending, but the next forenoon, December 21st, I was summoned, labor pains having begun at eight A. M. A feeble, evidently premature child was born at four P. M. The throat was better during the day. The pulse during the labor was of normal strength and frequency, and no unusual incident occurred except that my attention was called to a little swelling of the nose. I made no special examination of it in the darkened room, but the next day the swelling had increased, become livid in color, and painful. She had headache; pulse 100; temperature 102.2° F.; tongue as before. I need not give the record day by day, suffice it to say that the inflammation extended itself over both cheeks and the forehead, a part of the time both eyes being completely closed. The temperature in seven days came gradually to normal, the initial temperature having been the highest. The pulse after the delivery never exceeded 100. There was no abdominal disturbance. The lochia were scanty, a part of the time offensive. The milk secretion was established on the fourth day. There was no sign of the septicæmia which might have been considered probable, and in ten days she was sitting up as well as if her puerperium had been attended by no untoward condition, although her face was still much disfigured by the obstinacy of the swelling and some broken places on the affected skin.

¹ Read before the Boston Society for Medical Observation, June 18, 1883.

The weak infant died on the fourteenth day.

The treatment ordered in this case was not fully carried out. She could not afford the price of a training-school nurse, but had to rely on the well-meant, though often unintelligent, offices of friends. The lying-in room, however, was large, at least fifteen feet square, with windows on two sides, and good ventilation was secured. The room generally was rather cold, for she preferred blankets to continuous fire. The chilliness of the air gave her no discomfort or inconvenience. She had acetate of lead for the face, took medium doses of quinine, and a moderate amount of stimulants. She was bathed with carbolyzed water, but did not use carbolic injections.

Considering the general teaching in regard to erysipelas in connection with the lying-in room, it was remarkable that at no time should there have been any drawbacks. I think, however, that this case is but one example of a condition sufficiently common, and that erysipelas and the puerperal state quite often coexist without disastrous consequences. I report the case simply to emphasize this fact, which is often lost sight of in preliminary teaching and medical discussion. The usual statements are undoubtedly true of *phlegmonous erysipelas*, a limitation which is not generally explicitly made. But as regards the association or contact of *simple erysipelas* with the puerperal state, my reading, and observation, and experience alike lead to the conclusion that the dangers have been decidedly over-stated.

CASE III. *Eclampsia and Septicæmia*. April 5, 1883. Mrs. S., age twenty-three, primipara, began to have labor pains at four P. M. I saw her for the first time at 7.30 P. M. She reported that her health had been always robust, and she had been well throughout her pregnancy except that her feet had been swollen for a month past. At the present time the œdema is extensive, involving feet and legs, and the lower part of the abdomen also. The face is pale and puffy. Nothing definite was ascertained in regard to the urine. Her bowels were opened to-day with medicine. On examination the cervix was found thick, soft, and dilatable, pervious to one finger, the head presenting high up O. L. P. At eleven P. M. the cervix was thin, and the os as large as a quarter, the pains severe, and recurring every ten minutes, and she complained of nothing else. April 6th, at 1.30 A. M., I was suddenly called from the adjoining chamber to find her on her face in a violent convulsion, which lasted at least ten minutes. A second followed at 1.50, and a third at 2.10, of shorter duration; nor was there during the intervals any recovery of consciousness. The patient lay in a comatose state, with stertorous breathing, until the twitching of the mouth and the turning of the eyes ushered in the next attack, although the lividity of the face and lips following the tonic spasm partially disappeared in each interval.

In consultation with Dr. Disbrow I applied the forceps high up without ether, the os being now about the size of a half dollar. The forceps were hardly locked when, at 2.25, came another convulsion, which, fortunately, was of short duration. The traction was laborious, and a good-sized male child was delivered at 2.35 in a state of profound asphyxia. The placenta was expressed ten minutes later, the hæmorrhage was moderate, and the uterus contracted well. The only medicine she had had thus far was pot. brom., which she had swallowed in the intervals between the con-

vulsions. Without recovering consciousness she had a fifth attack at 3.05, and a sixth at 3.50. Between the convulsions the restlessness now became extreme. She was flinging herself bodily about the bed, tossing her arms and feet constantly. It was necessary to hobble hands and feet, and to use force to keep her on the bed. The skin was dry, the face turgid and cyanotic, the pulse soft and compressible, about 115. About an ounce of urine was drawn by the catheter, and became nearly solid with albumen on boiling. In consultation with Dr. W. L. Richardson it was decided that the indications were against venesection. At 4.30 she had a seventh convulsion. At 4.50 she took by mouth chloral, 1, pot. brom., 2, and soon after pilocarp. nit., .01. At five had her eighth convulsion. At 5.20 pilocarp., .01, which was repeated at 5.40. Convulsion at 5.45. At six chloral and pot. brom. repeated. About seven began free perspiration about the body, with moderate salivation, and this continued about two hours. Tenth convulsion at seven. Chloral and bromide at eight. Eleventh convulsion at 8.25, twelfth at 9.10, thirteenth at 10.30. The only favorable symptom thus far was the gradually lengthening intervals between the attacks. It was an uninterrupted succession of convulsion, coma, jactitation, and convulsion again, and the jactitation was to the sight quite as distressing as the convulsion itself. The tongue was badly bitten and bleeding. The face was dark. The pulse was growing weaker, and the case seemed utterly hopeless. With the catheter 150 grammes of high-colored urine was obtained at eleven A. M., loaded with albumen, and containing abundant granular and hyaline casts. At 11.50 fourteenth convulsion, at one P. M. fifteenth, and sixteenth at 2.10. During the afternoon all the unfavorable symptoms continued. The pulse reached 160, at times was almost imperceptible. The extremities became cold and clammy. She had taken during the day chloral, 6, and more than twice as much pot. brom., mostly by mouth, a little by the rectum, also three subcutaneous injections of morphia, .03 each, which gave each time about fifteen minutes of rest. She had also swallowed a small amount of gin. She had inhaled occasionally a little ether when the convulsion was imminent, but without any immediate effect. Later in the afternoon the pulse gained a little in strength, and warmth returned to the extremities, but at five P. M. occurred one more convulsion, the seventeenth and the last. About six P. M. 180 cc. of urine were obtained.

During the next night, the 6th, the restlessness continued almost unabated. It required two men to keep her on the bed. She took regularly pot. brom., 2, tr. hyoscyam., 4, every two or three hours. She passed water several times during the night involuntarily, and did not again require the catheter. She made a little gain in strength of pulse the next day, and became gradually quieter. She was fed with milk and beef tea and gin during the day, and in the afternoon began to open her eyes less wildly, though she showed no sign of dawning consciousness till towards evening, when she tried to respond to a question. She was unconscious for forty hours.

April 7th. Bowels have moved spontaneously in bed, and she has continued to pass water involuntarily. The nurse says the amount of urine must be considerable. The patient is uneasy, dull of comprehension, but complains of soreness of tongue, which has been badly chewed, of headache, and of violent

pain in the right arm, which was probably injured in the tossing.

April 8th. Temperature normal. Still restless.

April 9th. Temperature 100° F. Pain in abdomen. Lochia scanty. Temperature p. m. 101° F. Pulse 120. No sign of milk. Hot fomentations, warm injections, and quinine, .50, daily. Takes milk and gin regularly.

April 10th. Temperature a. m. 104° F.; p. m. 103° F. Pulse 125. Free from abdominal pain. Lochia still scanty. Nights still quite restless. Pain of arm so severe as to require opiate. Micturition under control. Bowels loose.

April 13th. Pulse 105. Temperature 101° F. Gradual improvement. Pain of arm diminishing. Takes liquid nourishment quite freely. Tongue still swelled, ragged, and somewhat painful. Headache still troublesome, though less severe. No secretion of milk. Urine, specific gravity 1015; albumen, one per cent.; numerous granular and hyaline casts.

April 17th. Pulse 100. Temperature 100° F. Has continued to improve slowly until to-day, and everything seems favorable to her speedy recovery. The urine is abundant, still containing albumen, one per cent., with casts as before. On this date she was carried from the South to the West End. I saw her again on the 21st. She was doing well, taking liquid nourishment quite freely, though still in bed, with temperature 100° F., pulse 90, and very anæmic.

April 26th I was summoned, and found her with temperature 103° F., pulse 115, making no special complaint. Anæmia very marked. No appetite. Tongue sore and swollen from the biting, with a dry, brown coat. No abdominal pain or vaginal discharge. Bowels costive. She was ordered quinine, 1, daily with stimulants.

April 28th. Temperature 104° F. No change.

April 29th. Temperature a. m. 104.3° F.; p. m. 103° F.

April 30th. Temperature 103.4° F. Severe pain in the right chest, but nothing abnormal on auscultation. Tongue clearing. Pulse more steady, and of fair strength.

May 3d. There has been little variation of fever or other symptoms. The pain in the side has continued severe. No cough or expectoration at any time. No abdominal pain. Much emaciated. Bowels moved only with cathartics. Fine moist râles over the right lower lobe with slight dullness. Urine, specific gravity 1025; albumen, one per cent.; hyaline and granular casts. Daily quantity from 1200 to 1500 cc.

May 5th. Temperature 102° F. Pulse 90, stronger. Tongue nearly clean. No cough. Fine moist râles still heard, though in diminished numbers.

May 6th. Temperature normal. Pain in chest almost gone. Tongue clean and nearly well. Nothing found in chest.
